PUTRID EMPYEMA

JOHN W. STRIEDER, M.D.,* AND JOSEPH P. LYNCH, M.D.†

BOSTON

PUTRID empyema has been recognized as a clinical entity for many years and has recently been the subject of a number of excellent reports.¹⁻⁴ Nevertheless, many surgeons fail to distinguish it from ordinary pyogenic empyema and, persisting in this misapprehension, treat it as they ordinarily treat this relatively benign lesion, with disastrous results. It is our belief that with a better understanding of the nature of the disease recognition will be prompter, treatment will be more adequate, and the mortality, which has been high, will be lowered.

The report that follows is based on an analysis of patients on the various services at the Boston City Hospital from June, 1934, to January, 1941, and of those on the Thoracic Surgery Service from January, 1938, to January, 1941—90 cases in all. A review of the etiology, bacteriology, pathology and treatment demonstrates that this disease differs strikingly from postpneumonic pneumococcal empyema and other pyogenic empyemas, with which it is so often confused. Furthermore, from the same review it is believed that the advantages of early and radical surgery can be demonstrated.

DEFINITION

Putrid empyema may be briefly described as a sloughing, gangrenous pleuritis caused by certain anaerobic bacteria acting in symbiosis. Its distinctive characteristic is the presence of extremely foul purulent fluid in the pleural cavity, which gives rise to its name. In almost 100 per cent of these patients the fluid obtained by thoracentesis was described by the operator as foul, stinking, sulfurous or putrid. On the other hand, the pleural fluid from no other patient with empyema was so described, in spite of the fact that a number of cases were due to the colon bacillus. The odor is indeed truly distinctive.

It might be more accurate to call the disease "anaerobic empyema," as has been suggested by

Maier and Grace¹ because, from our own studies and those of others, it appears that putrid empyema is always caused by anaerobic organisms. Melenev⁵ states that anaerobic infections are usually foul-smelling. When this is the case, one can be almost certain that he is dealing with anaerobic infection and not, as is so often erroneously inferred, with infection by the colon bacillus, which produces little if any odor. One can be certain that if the odor is foul the anaerobic infection is active, but if it is not, the presence of anaerobes cannot be ruled out. Since, however, there is still disagreement about the bacteriology and since the descriptive name is so distinctive, it seems better to continue the name "putrid empyema" until complete proof of the nature of the infection is at hand.

INCIDENCE

The number of cases of putrid empyema in any series of patients suffering from empyema varies with certain factors. Our figure is considerably higher than that found in other series, but this is thought to be a corollary of the high percentage of putrid pulmonary infections, such as lung abscess, bronchiectasis, fusospirochetal pneumonitis and pulmonary gangrene, encountered in a large municipal hospital where the economic and hygienic status of the patients is poor. Neuhof and Hirshfeld⁶ found the disease in 17 (9 per cent) of 184 children with empyema. In the present series, covering seven and a half years, 530 patients with acute empyema were treated at the Boston City Hospital, and of these, 90 (17 per cent) had putrid empyema. In general, it appears that 5 to 10 per cent of all cases of empyema are found to be putrid.⁷

That the disease is serious can be appreciated from mortality figures. Neuhof and Hirshfeld⁶ have reported a mortality of 47 per cent, and Flack³ one of 66 per cent. In the series of 57 patients reported herein, which were treated in this hospital but not on the Thoracic Surgery Service, most of them before 1938, the mortality was 54 per cent. These patients were treated on general surgical services by methods that would usually have been adequate for postpneumonic empyema but which

according to our criteria, were inadequate for putrid empyema

ETIOLOGY

Generally putrid empyema is secondary to some type of anaerobic infection of the lung. Most frequently it complicates a lung abscess or a gangrenous

TABLE 1 *Relation of Primary Disease to Mortality*

Average				44

*One patient left against advice and the outcome is unknown

(fusospirochetal) pneumonitis. In Table 1 are listed the primary diseases in this series, with the mortality rate of the putrid empyema that developed from them.

Graham et al.⁴ and Rosenblatt⁸ state that empyema is one of the most frequent complications of lung abscess. Neuhof and Hirshfeld² found that 25 of 104 patients with subacute or chronic lung abscesses developed putrid empyema. Neuhof and his associates⁹ also mention this type of empyema as a frequent and serious complication of the surgical drainage of lung abscess. Graham has expressed the belief, with which certain others have agreed, that frequently a lung abscess that has been complicated by putrid empyema heals when the empyema has been adequately drained. Neuhof and his co-workers⁹ have denied this, believing that the abscess should be drained at the time of operation for the empyema. In our opinion, spontaneous cures of abscesses depend on the size of the perforation and whether or not drainage resultant on the rupture is adequate. It is our experience that any decision concerning drainage of the abscess at the time of thoracotomy must be taken on the basis of the location of the abscess and the condition of the patient, as will be discussed later.

Graham et al.⁴ also state that empyema is a not infrequent complication of bronchiectasis. In the postoperative course of lobectomy for bronchiectasis such an empyema has been an all-too-frequent complication. Most of our cases in this group occurred in the course of an acute exacerbation of the bronchiectasis, and might more properly be considered complications of pneumonitis. In 2 of these, a definite cortical abscess could be seen at operation, and undoubtedly rupture of similar abscesses is the mechanism of empyema formation in many of these patients. It is interesting that, as shown in Table 1, when the putrid empyema complicates bronchiectasis the mortality is lower, out of all proportion, than that of the other groups. The significance of

this is conjectural, but may depend on the degree of immunity to the organisms that the patient has built up over a long period through his chronic disease, together with the tendency to localization and stabilization caused by pre-existing pleural adhesions.

Pneumonitis

Pneumonitis is so designated to distinguish it from pneumococcal pneumonia. These cases are most difficult to understand. Only 3 cases in our personal series fall definitely in this group, but some of them may have been the typical pulmonary gangrene that is included in this category. One of our patients was such a case. Another developed as a complication of fusospirochetal pneumonia, which has been described by Peirce and Field,¹⁰ and others were undoubtedly acute exacerbations of pneumonitis on an underlying bronchiectasis. Careful follow-up studies might have revealed this diagnosis in more cases. Eleven of the 12 patients with bronchiectasis were studied on the Thoracic Surgery Service, which suggests that the diagnosis will be made oftener if its possibility is entertained. In general, the onset of the disease in these patients resembled that of pneumonia, yet its chronicity made this diagnosis untenable. In no case were pneumococci found in the sputum, and roentgenograms of all but 3 demonstrated pleural fluid. The diagnosis in most of these patients was based on the history, for in all but 3, even the physical signs on admission were those of fluid. On the basis of our clinical experience, we believe that the acute stage of all these putrid pulmonary infections is a pneumonitis.

The patients who developed this disease as a complication of tuberculosis probably had secondarily infected blocked cavities that ruptured into the pleura.

The remaining patients include 1 who developed pulmonary gangrene distal to an obstructing carcinoma and 2 who developed it after trauma. In one of the latter it followed the instrumental rupture of a bronchus, the patient having had bronchiectasis secondary to a long-standing obstructing foreign body, for the removal of which bronchoscopy was performed. Thirty-six hours following bronchoscopy he became moribund because of unrecognized tension pneumothorax and anaerobic pleural infection, so that only a closed thoracotomy could be done. He continued to grow worse, and died twenty-four hours later. The other patient, whose case we¹¹ have previously reported, developed a *Clostridium welchii* infection of the pleura following a stab wound in the chest. This complication, seldom seen in civil life, is frequent in wounds of the chest in wartime.

The unknown group includes 10 patients, 3 of whom died, no autopsies being done. The others received no studies except routine roentgenograms.

Bronchograms would undoubtedly have shown bronchiectasis in some cases. Pilot¹² suggests the mechanism in such cases by assuming the formation of an abscess so close to the pleura that rupture occurs before pulmonary destruction is extensive enough to be apparent clinically.

BACTERIOLOGY

The bacteriology of putrid empyema is complicated and uncertain, mainly because of two factors. First, the fact that the infection is due to anaerobic bacteria has prevented complete and accurate correlation of the clinical and bacteriologic studies. Only during the last ten to fifteen years has much study been devoted to these organisms, and even at the present time relatively few hospitals are adequately equipped to do complete anaerobic studies, as pointed out by Meleney.¹³ Without such technical facilities the diagnosis cannot be made, for the general experience has been that anaerobic cultures are needed. In our experience, repeated routine cultures of pleural fluid not infrequently show no growth, but the anaerobic culture demonstrates the presence of infection. Second, it seems to be established that the problem of symbiosis is involved in putrid empyema and its related, and usually antecedent, diseases. So general has been the belief that one organism must cause each disease and that Koch's postulates must be satisfied that the work on infections due to the synergistic action of two or more organisms has been retarded. That certain organisms favor the growth and metabolic activity of other species in the same surroundings is well known. It has also been demonstrated that in the development of certain pathologic processes by mixed cultures one species may initiate the inflammatory reaction in the host and the other may complete it. This conception has been suggested by Altemeier,¹⁴ who concludes that although a great deal of work has been done, much remains to be accomplished.

Leeuwenhoek in 1683 first described the fusiform bacillus and the spirochete,¹⁵ and Laennec in 1819 described the first case of pulmonary gangrene. Longacre and Herrmann¹⁶ have discussed the work of Leyden and Jaffe, who in 1867 first associated the spirochete with putrid bronchiectasis and pulmonary abscess, and Kline and Berger¹⁷ mention Plaut (1894) and Vincent (1896) as having identified these organisms and named them as the cause of the mouth infection now known as Vincent's angina.

A review by Fisher and Abernethy¹⁸ states that in 1893 Veillon mentioned the anaerobic streptococcus, which he had isolated from a foul Bartholin's cyst. Since that time this organism has most frequently been isolated from foul lesions of the lung and pleura and from puerperal infections. These authors credit Rendu and Rist (1899) with the

description of the association of the anaerobic streptococcus with the gram-negative bacillus.

Until World War I, however, the anaerobes received little attention, but following the armistice much work was done on them. The anaerobic spore-bearing gram-positive bacilli received the greatest attention and consequently are the best understood. Some of these may cause putrid empyema, usually following trauma, but this seldom occurs in civil life.^{11, 19} The gram-positive cocci have been recognized, and many attempts to classify them have been made, but much study is still needed. Meleney and his co-workers have been most successful with their researches into microaerophilic streptococci. The gram-negative and gram-positive non-sporulating bacilli have received the least attention of all. In 1905, Weaver and Tunnicliffe,²⁰ after successfully culturing the fusiform bacillus, were unable to produce any pathologic lesions with the pure culture, yet when a mixed culture was used, a gangrenous infection resulted. This inability to produce disease with the pure culture of these organisms gave rise to the impression that they were mere saprophytes, and many still hold this impression.²¹ Smith²² believes that they are not secondary saprophytic invaders. In 150 patients with pulmonary tuberculosis, 6 with asthma and 5 with mycotic lung infections, the fusiform bacilli and the spirochetes were absent in every case, despite repeated examinations. If they were secondary invaders, one would expect them to be present in almost every form of chronic pulmonary disease.

Despite all this work, up to 1928 only about 150 cases of pulmonary fusospirochetal infection had been reported. After this, however, the number of reports relating these organisms to pulmonary gangrene, lung abscess and bronchiectasis greatly increased. Moreover, the excellent work of Smith,²³ Kline²⁴ and Pilot and Davis²⁴ has clearly shown that these anaerobes in association — that is, the organisms usually found in Vincent's angina, periodontal infection and pyorrhea alveolaris — are the same as those usually found in putrid lung infections, and that these infections may be produced with them. Smith²⁵ has reported cases in which contact with a case of Vincent's infection resulted in pulmonary fusospirochetosis and that exactly the same organisms were found in both diseases. More will be said about this in connection with the experimental production of these diseases.

It should be remembered, as has been emphasized by Smith²⁶ and others, that although these infections are usually referred to as fusospirochetal, this is mainly because these organisms are so easily identified on smear. The anaerobic cocci are always associated with them and are of equal importance.

As revealed in the literature, the bacteriology of putrid empyema seems complex, each author emphasizing a different organism or group of organisms. Fisher and Abernethy¹⁸ stressed the role of the

anaerobic streptococcus, which they were able to find in all the 7 cases they reported. Flack³ reported 3 cases in which the fusospirochetal organisms seemed to be the important factor. Kline and Berger²⁷ and Farbman and Danforth²⁸ have also reported cases in which the fusospirochetal organisms were observed, and the former are especially convinced that these are the pathogenic agent. Maier and Grace¹ describe the cause as a mixed bacterial flora, with the fusiform bacilli, spirochetes and the anaerobic streptococcus those most frequently found. They believe, furthermore, that symbiosis is an important factor in the action of these organisms. Sauerbruch and O'Shaughnessy²⁹ also name the anaerobes as the cause of putrid empyema.

In Table 2 are presented the results of the bacteriologic findings in this series. The routine pro-

TABLE 2 Bacteriologic Data

ORGANISM	NO OF CASES	RECOVERIES	DEATHS	MORTALITY %
Fusiform bacilli (alone)	18	9	9	50
Streptococcus (strict anaerobe)	8	5	3	38
Streptococcus (facultative anaerobe)	63	35	27	44 (62 cases)
<i>C. welchii</i>	1	1	0	0
Totals	90	50	39	

cedure now adopted by the Bacteriology Department is to culture all empyema fluids under anaerobic conditions (cooked-meat medium), as well as aerobically (blood broth and blood-agar plates). Stained smears serve to identify morphologically the fusiform bacilli and spirochetes, and these occasionally grow in the cooked-meat medium. The strictly anaerobic streptococci also grow in the cooked-meat medium and can be subcultured to blood-agar plates that are incubated under anaerobic conditions. The facultative anaerobic streptococci grow both in the cooked-meat medium and in the blood broth, and on subculture will grow on blood-agar plates incubated under ordinary atmospheric conditions, although much better growth is obtained if the plates are incubated in an atmosphere containing an increased amount of carbon dioxide (Nye and Lamb³⁰). Most strains of the last organism are beta hemolytic on blood agar and they are closely related to, if not identical with, the microaerophilic streptococci described by Meleney.¹³

The fusiform bacillus was identified in every patient except the one in whom the infecting organism was *Clostridium welchii*. In only 9 patients were aerobic organisms found, and never were they present without an anaerobe — this in spite of the fact that aerobic cultures were made in every case. These aerobes were the streptococcus, pneumococcus and staphylococcus and the influenza bacillus. Again, it should be pointed out that if aerobic cultures alone were made on all cases, the true nature of the disease might have been overlooked, and the assumption might have been made that the empyema was due to the aerobic organism.

The fusiform bacillus has been described as a strict anaerobe, and many different types have been identified by their morphology alone. Some attempts have been made to distinguish them serologically. The spirochetes have proved to be the most difficult to grow, but they were reported as seen on the direct smear in one quarter of our cases. Four types of the spirochete have been identified by Smith.²⁶

PATHOLOGY

Putrid empyema presents itself as a gangrenous, hemorrhagic pleuritis, with the production of a large amount of fluid and, on occasion, gas. It complicates a gangrenous process of the lung that may be acute or chronic. When the parent disease is acute, there is usually total involvement of the pleura, but when the underlying condition has existed for some time, a moderate amount of walling off may have occurred, and a localized type of empyema then develops. Tissue necrosis is, however, one of the outstanding features of anaerobic infections, hence, the adhesions tend to disappear, and there may result one or more large or small compartments filled with foul pus and debris. The formation of fibrinous adhesions occurs early in every case, and this is an important feature in the treatment of these patients.

The fluid in this disease tends to be thin for a long time, but the pleural reaction is so marked that the mediastinum becomes fixed early.¹ In this series of 90 patients, the fluid was described as thin in 45, creamy in 13 and thick in 24, and was not mentioned in 8. Some patients had a clear serous fluid at the first thoracentesis. Smith²⁶ has also described this, noting that the fluid may be clear for the first day or so. In the present series, the culture of the clear fluid often showed the anaerobes and the characteristic foul odor was noted. In other cases the fluid was odorless. In 19 cases, the pleural fluid appeared clear on the first thoracentesis, but a second thoracentesis, soon after the first, produced fluid that was both foul and purulent.

The presence of a bronchopleural fistula has frequently been noted in patients with this disease. Its occurrence depends on the underlying disease. The incidence is high in empyema complicating the rupture of a lung abscess, it is medium in the bronchiectasis group and low in the pneumonitis group. In this series a fistula was noted in 25 patients, and may have been present in others, especially in the 19 not operated on. It caused little change in the course of the disease, however, and in all cases closed before there was complete obliteration of the empyema cavity. In 20 cases the fistulas were in the abscess and bronchiectasis groups, and in 2 they were in the tuberculous group.

ANIMAL EXPERIMENTS

The bacteriologic investigation of putrid empyema by experimental methods has been neglected, but

many investigations of the primary disease have been made, and much of the present discussion concerns these Pilot and Davis²⁴ were able to show that a pure culture of fusiform bacilli had little pathogenicity. In the pleural cavity the organisms caused only a slight fibrinous exudate. The cocci — 80 per cent of which were anaerobic streptococci — alone produced a serofibrinopurulent pleuritis without odor. When the spirochetes fusiform bacilli and cocci were combined, however, the lesion had a putrid odor. Smith⁷ has produced pulmonary abscesses, bronchiectasis, gangrene and pneumonia by the intratracheal injection of material from the alveolar border of patients with pyorrhea. He demonstrated that four organisms, the anaerobic streptococcus, the fusiform bacillus, a spirochete and a vibrio, were needed. None of these alone, nor any mixture without all of them, produced the characteristic lesions.

Many others^{5, 16, 23, 31-36} have been able to produce these lesions by using the anaerobes, some by the intratracheal route and others by means of infected emboli. The material used was generally obtained from the scrapings of the teeth of patients with pyorrhea alveolaris, and was usually shown to contain the anaerobes mentioned above. Crowe and Scarff³⁴ point out the many unsuccessful attempts to produce lung abscesses by the intratracheal inoculation of virulent forms of staphylococcus, streptococcus, pneumococcus and the colon bacillus. Yet when the anaerobes were employed, the usual result was a localized chronic pulmonary suppuration.

The incidence of empyema is not mentioned in most of the results reported. Longacre and Herrmann,¹⁶ however, give the incidence in their experimental series as 10 per cent following the intratracheal method and 33 per cent following the use of emboli infected with anaerobes.

METHOD OF INFECTION

Almost all writers agree that there is infection about the mouth in these patients. Usually there is pyorrhea alveolaris, chronic ulceration of the mouth or a Vincent's infection. Meleney⁶ notes that the most frequent anaerobic infections are those about the mouth. These organisms may be aspirated, with resulting pneumonitis or abscess and the complication of putrid empyema. Duffy³⁷ was able to show fusospirochetes in all his patients. Stern²⁸ concludes that a thorough investigation of the dental history in cases of abscess of the lung may reduce the percentage of cases formerly grouped as pulmonary abscess of unknown origin. He was chiefly concerned with antecedent dental operations, but we have been greatly impressed by the high incidence of unhygienic mouths encountered in patients with putrid empyema without a history of any dental procedure. Thus, the taking of alcohol, poor oral hygiene and a period

of unconsciousness prior to the onset of the disease seem to be the usual combination of factors culminating in putrid empyema that is seen in large municipal hospitals. Smith²⁶ also believes that aspiration of infected material from the mouth probably accounts for most pulmonary abscesses, although a small number may be due to emboli from the respiratory passages. In this series a description of the teeth was present in the records of 70 patients. Of these, the teeth were described as good in 7, as negative in 3 and as showing pyorrhea or chronic infection in 60. This means that at least 85 per cent of the patients had infection about the teeth.

CLINICAL FEATURES

Certain clinical features are distinctive of putrid empyema. In this series there was a marked predominance of males who comprised 72 of the 90 patients. The disease was, however, about equally fatal in both sexes, the mortality being 46 per cent in males and 39 per cent in females.

The ages of the patients varied from five to seventy-eight years. The relation between age and mortality is shown in Table 3. In general, mortal-

TABLE 3 Relation of Age and Mortality

AGE	No. OF RECOVERIES		DEATHS	MORTALITY
	CASES			%
37				
1-9	4	4	0	0
10-19	11	9	2	18
20-29	12	8	4	33
30-39	18	10	8	44
40-49	23	11	11	50 (22 cases)
50-59	9	3	6	67
60-69	7	5	2	29
70 up	6	0	6	100
Totals	90	50	39	

ity increased with age. An explanation for the low mortality in the sixty-to-sixty-nine-year group is suggested by the type of surgery employed. In this group, 5 of 7 patients recovered and all of these, and only these, had adequate surgery. This indicates that the other patients in the older age groups were deprived of the chance that adequate surgery might have offered. In many cases the records showed that there had been much waiting for the patient's condition to improve, whereas it deteriorated rapidly and progressively. The condition on admission was said to be poor in 42 patients, fair in 27 and good in 15. The condition of 6 patients was not recorded. In other words, most of the patients appeared to be acutely ill at the time of admission. Their poor general condition is not an accurate indication for delaying surgery, on the contrary, it suggests that immediate surgery is imperative.

Although the disease evolves in a variety of ways, there are some constant signs. A frequent complaint is severe pain, often localized, and persisting even after the development of fluid. Associated with this is a localized tenderness of the chest wall, which is a frequent indication of severe gangrenous

infections of the pleura. The clinical impression on admission in many patients was that of pneumonia, usually based on a history of pain in the chest, chills and cough, yet the physical signs were those of fluid, which characteristically develops early in the disease.² The roentgenogram was occasionally misleading, showing consolidation even when fluid was present. A history of cough of long duration, often with foul sputum, was frequent and was helpful in making the diagnosis.

These patients are often far more ill than one would expect from the amount of discoverable disease. They early become toxic and delirious. They frequently show signs of peripheral vascular collapse, with cold, clammy extremities and an extremely rapid pulse. The temperature, although elevated, is not in proportion to the pulse, a feature common to all anaerobic infections.

The diagnosis of this disease is made by thoracentesis. Fluid having a foul odor is pathognomonic, although a direct smear that reveals the fusospirochetes is corroborative evidence, easily obtained. Anaerobic culture of the fluid must be done, for aerobic culture does not reveal the true nature of the infection. In reviewing these cases, it was not unusual to find that two or more aerobic cultures had been done without growth before an anaerobic culture revealed the infecting organisms. Purulent chest fluids should always be cultured anaerobically, especially those that are foul.

One complication of thoracentesis, cellulitis of the chest wall, has been noted by many authors.^{1, 2, 17, 18} It is so grave that every precaution should be taken to circumvent its occurrence. Apparently the thin, watery fluid easily passes along the needle track into the deep tissues of the chest wall. There, under the muscles, in the tissues overlying the ribs, conditions are ideal for the growth of anaerobes. Severe pain and tenderness soon appear. Within twenty-four hours there is marked redness, and a cellulitis with gangrene of the deep tissue rapidly develops. Because of this, most observers have wisely stated that thoracentesis should be followed by surgery as soon as possible and that repeated thoracenteses are contraindicated. It is true that in some patients thoracentesis can be done more than once without this complication, on the other hand, when it develops it is of such severity that it approaches in importance or overshadows the underlying disease.

Majer and Grace¹ encountered cellulitis of the chest wall in 4 of their 23 patients, despite the fact that about half the patients were operated on within twenty-four hours of the thoracentesis. In the present series, 21 patients developed this complication. If those operated on within twenty-four hours are eliminated, 38 per cent developed it. In our experience this complication is so severe and frequent that we, too, believe that thoracentesis should be done only for diagnostic purposes and

should be immediately followed by open drainage. Also, because this complication may develop, closed thoracotomy or the suture of wounds after rib resection is extremely hazardous.

TREATMENT

The rate of recovery is greatest in the patients operated on early. The average of the time intervals from the onset of the disease — calculated as accurately as possible from the records — to the time of operation in those who lived was 5.2 days, and in those who died it was 10.7 days. This may be expressed in another way by considering all the patients who had surgical treatment. On the first to the third day, 25 patients were operated on and 22 recovered, a mortality of 12 per cent. On the fourth to the seventh day, 22 were operated on and 16 recovered, a mortality of 27 per cent. On the eighth to the tenth day, 13 were operated on, and only 6 recovered, a mortality of 54 per cent. Hence, it can be seen that 75 per cent of the patients who were operated on in the first week of their disease recovered, whereas slightly more than one third of those who died were operated on within the first week. Further evidence of the need for early surgery can be obtained from the fact that of the 18 patients who died without operation, 10 did so within the first ten days of their disease. In 7 cases, it was impossible to calculate the exact duration of the disease with any accuracy, but in most of the cases the course was probably less than ten days. Only 1 patient lived with the disease over the ten-day period.

With few exceptions there is unanimity of opinion on the treatment of this disease. All writers agree that surgery is indicated and that open drainage is the treatment of choice. Graham, Singer and Ballou⁴ believe that it is safer to aspirate frequently or to use closed drainage, and give as their reasons those that generally pertain to pyogenic empyema. Flack³ thinks that conservative treatment with an intercostal tube and later resection of a rib is the treatment of choice. The differences of opinion on the treatment of the disease depend largely on the question of mediastinal stabilization. If one applies the usual principles that govern the treatment of postpneumonic empyema and awaits thickening of the purulent fluid to the consistence at which mediastinal fixation may be postulated, valuable time may be lost.

The sole attribute common to all anaerobes is their inability to multiply or even live in an atmosphere rich in oxygen. It has been shown that they succumb after only a few hours of contact with oxygen, even in low concentration. Consequently, most writers have agreed that open operation with adequate aeration and evacuation of the pus is the best treatment.

Moreover, in this disease, despite the consistence of the fluid, there is prompt stabilization of the

mediastinum, so that early operation may be accomplished. Maier and Grace¹ noted that all except one patient in their series with thin fluid had a fixed mediastinum.

In 1938, Dolley and Jones³⁹ described a method for open drainage of acute pyopneumothorax in patients in whom the mediastinum is not stabilized. This procedure is simple and logical and has proved most successful in our patients. It is to be remembered that the cases causing concern about the stability of the mediastinum are few, for, as has been noted, early fixation is the rule. The method to be described provides an adequate method of treatment in the event that a mobile mediastinum is encountered. With this method none of our patients developed chronic empyema, and the average time of treatment from operation to complete closure of the wound was seven weeks. Another type of treatment which agrees with ours in principle but differs slightly from it in technic, is that described by Sauerbruch and O'Shaughnessy.²⁹ This consists in the removal of two dependent ribs under positive-pressure anaesthesia and open packing of the wound.

Operative Technic

The operative method that we have used follows closely that of Dolley and Jones,³⁹ described for the treatment of acute pyopneumothorax following the rupture of a lung abscess. We have used 1 per cent procaine infiltration as the anesthetic of choice. A 20-cm incision is made over the most dependent rib, as determined by thoracentesis, and is extended from the posterior to the anterior axillary line. It is carried through the muscles, and a segment of the appropriate rib as long as the incision is resected subperiosteally in the usual fashion. A large dressing has already been prepared for immediate use.

From this point the procedure is determined by the degree of mediastinal fixation. This may be judged by the amount of pleural thickening or by means of a small incision into the pleural cavity. If there is inadequate fixation, the pleura is quickly incised the entire length of the incision, the dressing is applied, and the patient is quickly turned on his back. With this routine rapidly performed, the dangers of open pneumothorax are largely circumvented, for the dressing soon becomes saturated and serves as a tampon, preventing the exchange of air through the wound, yet the wide opening thus secured allows complete drainage into the dressing. The dressing is not changed until the third day, when a quick change is made. Stabilization usually occurs from the fifth to the seventh day, and from then on a tube or pack can be used. It has been our policy to use a gauze pack impregnated with activated zinc peroxide, placed partly in the pleural cavity and partly in the wound. By this means the odor disappears and the wound is

clean and granulating five to seven days after the treatment is begun. Tubes are then inserted. The convalescent treatment is the same as that for the usual postpneumonic empyema. The use of zinc peroxide has been found of value by many others in anaerobic infections,^{1, 3, 17, 40} and we cannot emphasize its value too strongly for this type of disease.

If the fixation is adequate, more time can be spent examining the cavity and removing all the pus and fibrin by suction. Otherwise, the treatment is the same, except that the zinc peroxide is used from the time of operation.

Under no circumstances is an attempt made at any type of wound approximation, and hemostasis is obtained with a minimum of ligatures.

Most of the patients so treated show immediate improvement. In a few days the appetite returns and they become more active in bed. For a considerable period, often two or three weeks, however, these patients have a low-grade fever apparently due to the primary intrapulmonary infection. Irrigations are not always possible because of the existence of a fistula. If one is not present, irrigations may be helpful because of their mechanical cleansing action.

Drug Treatment

The effect of the sulfonamides on the anaerobes is still uncertain. Some evidence has appeared that these drugs are of no value in this type of infection, but this is confusing and uncertain. Meleney⁵ believes that their value in this type of infection, in which there is early destruction of tissue, has not been demonstrated. Maier and Grace¹ found that the typical dramatic response to these drugs did not occur in this type of infection. In fact, they believe that this failure of response is a point of differentiation between the atypical pneumonia associated with foul empyema and the typical pneumococcal pneumonia.

Twenty-one of the patients in this series were treated with one of the sulfonamides — usually sulfathiazole or sulfapyridine. Of these, only 1, with an infection due to *Cl. welchii*, showed a favorable response. We are of the opinion that these drugs are of no benefit once the empyema has developed, regardless of what value they may prove to have for the primary disease. The other drugs ordinarily used in fusospirochetal infections are the arsenicals. Despite any questionable value they may have for the primary disease, they are of no worth in the treatment of putrid empyema.

We have treated recently 2 cases of putrid empyema, not included in this series, by the intramuscular and intrapleural injection of penicillin. In the first case the empyema complicated a pneumonitis that was apparently the result of the aspiration of infected material from the mouth. The pleural fluid was typically putrid, and cultures re-

infections of the pleura. The clinical impression on admission in many patients was that of pneumonia, usually based on a history of pain in the chest, chills and cough, yet the physical signs were those of fluid, which characteristically develops early in the disease.² The roentgenogram was occasionally misleading, showing consolidation even when fluid was present. A history of cough of long duration, often with foul sputum, was frequent and was helpful in making the diagnosis.

These patients are often far more ill than one would expect from the amount of discoverable disease. They early become toxic and delirious. They frequently show signs of peripheral vascular collapse, with cold, clammy extremities and an extremely rapid pulse. The temperature, although elevated, is not in proportion to the pulse, a feature common to all anaerobic infections.

The diagnosis of this disease is made by thoracentesis. Fluid having a foul odor is pathognomonic, although a direct smear that reveals the fusospirochetes is corroborative evidence, easily obtained. Anaerobic culture of the fluid must be done, for aerobic culture does not reveal the true nature of the infection. In reviewing these cases, it was not unusual to find that two or more aerobic cultures had been done without growth before an anaerobic culture revealed the infecting organisms. Purulent chest fluids should always be cultured anaerobically, especially those that are foul.

One complication of thoracentesis, cellulitis of the chest wall, has been noted by many authors.^{1, 2, 17, 18} It is so grave that every precaution should be taken to circumvent its occurrence. Apparently the thin, watery fluid easily passes along the needle track into the deep tissues of the chest wall. There, under the muscles, in the tissues overlying the ribs, conditions are ideal for the growth of anaerobes. Severe pain and tenderness soon appear. Within twenty-four hours there is marked redness, and a cellulitis with gangrene of the deep tissue rapidly develops. Because of this, most observers have wisely stated that thoracentesis should be followed by surgery as soon as possible and that repeated thoracenteses are contraindicated. It is true that in some patients thoracentesis can be done more than once without this complication, on the other hand, when it develops it is of such severity that it approaches in importance or overshadows the underlying disease.

Maier and Grace¹ encountered cellulitis of the chest wall in 4 of their 23 patients, despite the fact that about half the patients were operated on within twenty-four hours of the thoracentesis. In the present series, 21 patients developed this complication. If those operated on within twenty-four hours are eliminated, 38 per cent developed it. In our experience this complication is so severe and frequent that we, too, believe that thoracentesis should be done only for diagnostic purposes and

should be immediately followed by open drainage. Also, because this complication may develop, closed thoracotomy or the suture of wounds after rib resection is extremely hazardous.

TREATMENT

The rate of recovery is greatest in the patients operated on early. The average of the time intervals from the onset of the disease — calculated as accurately as possible from the records — to the time of operation in those who lived was 5.2 days, and in those who died it was 10.7 days. vealed the usual mixed flora. Twenty-five thousand units of penicillin was daily administered intrapleurally for ten days, a total of 250,000 units. Following this the fever persisted, and five days later rib resection was performed, with the intention of draining a residual pocket. Exploration revealed only fresh adhesions and a thickened pleura. The chest was closed without drainage, and the patient made an uneventful recovery.

In the second case the empyema complicated a pneumonitis that resulted from the post-partum aspiration of vomitus or mouth secretions or both. The patient was considered moribund when first observed. She received 10,000 to 60,000 units of penicillin intrapleurally daily for fourteen days, a total of 368,000 units. During that time there was striking improvement in the general condition. On the fifteenth day, rib resection was performed for the drainage of a localized empyema. The patient also received an average of 120,000 units of penicillin intramuscularly daily for thirty-nine days, a total of 4,640,000 units. A lung abscess that developed in the upper lobe at the site of the original pneumonitis was drained in two stages on the thirtieth and thirty-sixth days. The patient was discharged on the seventy-fourth day, the temperature having been normal for fifteen days. She has been well for over a year.

One may conclude that penicillin is a valuable adjunct in the treatment of putrid empyema and effects cures in a certain percentage of cases.

RESULTS

Tables 4 and 5 show the results of treatment in this series. The former includes the total series of patients, whereas the latter records only those who were treated on the Thoracic Surgery Service. In explanation of these tables, "rib resection" refers to the usual type of operation done for empyema,

TABLE 4 *Results in the Total Series*

TYPE OF TREATMENT	NO OF CASES	RECOVERIES	DEATHS	MORTALITY %
No operation	19	0	18	100 (18 cases)
Closed thoracotomy	13	2	11	85
Rib resection	31	25	6	19
Open resection	22	19	3	14
Combined closed and open thoracotomy	5	4	1	20
Totals	90	50	39	

with wound closure about one or more tubes. "Open resection" refers to the method described herein, with wound left widely open.

If one first considers the mortality for each type of operation, one sees clearly the value of the adequate types of surgery as represented by rib resection and open resection. The results with the conventional rib resection were good, and the insertion of tubes may be helpful, if there is time. We believe, however, that the use of zinc peroxide is specifically so valuable that it is better to wait until the anaerobic infection has cleared, as judged by the foul

odor, before using the tubes. Finally, closure of the wound is of no value and may cause definite harm in some patients, for in this series one third of the patients whose wound was sutured developed

TABLE 5 *Results in Patients Treated on the Thoracic Surgery Service*

TYPE OF OPERATION	NO OF CASES	RECOVERIES	DEATHS	MORTALITY %
Closed thoracotomy	2	0	2	100
Rib resection	9	6	3	33
Open resection	21	18	3	14
Combined closed and open thoracotomy	2	2	0	0

Average				23

a gangrenous, sloughing wound infection, with associated necrotizing phlegmon and eventual complete dehiscence.

These results demonstrate the benefit of immediate surgery of the open type. The 2 patients on the Thoracic Surgery Service who had a closed thoracotomy were seen late, when they were suffering the combined effects of overwhelming sepsis and severe tension pneumothorax, with marked mediastinal displacement. The closed thoracotomy was done immediately as a temporizing measure, but the patients died soon after it, before more could be done. It is doubtful that any type of operation would have helped one of these patients who had extensive bilateral pulmonary tuberculosis.

The results of combined surgery — that is, closed and open thoracotomy — appear to be good, but in both patients on the Thoracic Surgery Service the closed drainage represented a temporizing measure done immediately to correct altered chest mechanics and to allow time for general treatment. In both cases, open resection was done very shortly after the tube drainage. In the other 2 recovered patients who had combined surgery in the total series, both had closed drainage for many months, which proved to be inadequate and had to be followed by rib resection for adequate drainage. In 1 case, however, a chronic empyema resulted.

The 3 deaths among the 21 patients receiving open resection indicate that the mortality when treatment is adequate is usually from the primary disease. One patient died from multiple acute lung abscesses, which had been progressing when the empyema developed. The second died from a gangrenous pneumonitis involving the entire left lung and the lower right lobe. The empyema was on the left, and drainage was accomplished without incident. One week after the drainage, however, spread of the intrapulmonary disease to the right side occurred, and the course was downhill thereafter. The third patient, who had extensive intrapulmonary disease, died twenty-two days after the drainage of a brain abscess, although the empyema was healing well.

SUMMARY

Putrid empyema is shown to be a distinct disease entity differing in its etiology, bacteriology, pathology and clinical aspects from postpneumonic or other pyogenic empyemas.

Bacteriologically, the disease is due to certain anaerobes that produce a gangrenous sloughing pleuritis. Clinically, it is characterized when untreated as an acute onset followed by a rapid severe course and an early fatal termination.

The fact is stressed that in many patients the fluid is thin for some time. This characteristic should be noted but should not be considered a criterion in treatment. Concern about the consistence of the fluid is fatal, for it is a frequently noted fact that stabilization of the mediastinum occurs early in these patients. If the mediastinum is not stabilized, patients can be operated on by the method herein described and thereby receive the benefits of early and open operation.

A review of the 90 cases reported demonstrates the value of early open operation. Zinc peroxide is of distinct value in postoperative treatment. Once the foul odor has disappeared and the hazard of open pneumothorax is in abeyance, these patients may be treated like those with the ordinary pyogenic empyema.

Further experience may show that penicillin is a valuable adjunct in the treatment of putrid empyema.

THE EARLY DIAGNOSIS OF MINIMAL PULMONARY TUBERCULOSIS*

I D BOBROWITZ, M D,† AND RALPH E DWORK, M D ‡

OTISVILLE, NEW YORK

THERE are numerous vital reasons that indicate the importance of diagnosing tuberculosis in the minimal stage. The results of sanatorium treatment and follow-up analyses many years after discharge have uniformly shown the following constant and unequivocal advantages for minimal cases in comparison with advanced tuberculosis.¹⁻⁴ The percentage of arrested or healed cases is highest, and the time required to obtain an arrest of the disease much the shortest in minimal cases. This group also has the smallest incidence of instability. Collapse measures are infrequent and when used are less extensive, with complications, morbidity and mortality thereby reduced. The sputum is not so often positive as in moderately and far advanced cases. This is important, for all therapeutic procedures aim at the reversal of a positive to a negative sputum. The great majority of patients with persistently positive sputums sooner or later progress and have a bad prognosis, with little chance of survival. During the institutional and follow-up phases of treatment, the number of deaths are markedly less in cases diagnosed in the minimal stage than in those found with advanced tuberculosis, and the patients live much longer. The need for patients to be readmitted after discharge from the sanatorium increases as the stage of the disease advances. The minimal cases, moreover, have far fewer recurrences. All follow-up studies also show that the percentage of those employed or able to work is much higher in this group.

There are great benefits to the public in the early diagnosis and cure of the disease. The spread of tuberculosis from persons with positive sputums to their families and friends and the community is avoided, and a health hazard of first importance is controlled. The shorter hospitalization period required for minimal cases means that cure is effected at a lower cost. Furthermore, these patients often adjust themselves economically, and public expenditures for them and their families are thereby definitely lowered.

The practicing physician is an extremely valuable case-finding agent, since he is in a position to discover a vast number of persons with tuberculosis. Indeed, a large portion of patients see him before anyone else. These opportunities for diagnosis are particularly significant at this time, since war, as always, has increased the incidence of tuberculosis.

To determine the factors that could aid the making of an early diagnosis, 200 cases with minimal lesions

were studied. These patients were consecutive admissions to the sanatorium, and all the cases were minimal on admission, according to the standards of the National Tuberculosis Association.

Of the entire series, 155 patients were between the ages of fifteen and thirty-five. Forty-five patients were over thirty-five years old, with 20 of them older than forty. There has not been enough emphasis on the fact that tuberculosis often occurs in the elderly. Older people represent a great source of infection, for far too frequently their symptoms are explained on the basis of other conditions, such as a chronic bronchitis, asthma or winter or cigarette cough. The 200 patients were quite evenly distributed according to sex—96 males and 104 females. One hundred and one were single, 86 were married, and 13 had separated or been divorced. Of the entire group 123 were Whites, 52 were Negroes, 5 were Chinese, and 1 was a Filipino. Over forty different occupations were represented. These personal data indicate that tuberculosis should be suspected at any age and in any occupation. They may also have any type of social or economic background.

One hundred and thirty-three patients had no specific contact history. Fifty-seven had had definite close association with tuberculosis, 7 had had slight contact, and 3 had had possible exposure. In other words, 67 patients (34 per cent) had had some contact with tuberculosis.

A history of contact with this disease is significant mainly in its indication that the patient has had opportunities to become infected. In fact, many more cases are found in these persons than in the general population. The high tuberculosis morbidity and mortality rate for those with a history of household contact has often been emphasized and the particular danger for children has also been stressed.^{5, 6} Every person who has had contact with tuberculous patients should have a complete examination, including x-ray, at once. This should be repeated every year, and preferably every six months. As our figures show, however, lack of contact does not rule out the presence of tuberculosis.

Of these 200 patients, only 37 (19 per cent), were without symptoms. One hundred and fifty-five patients had specific complaints, and 8 gave a history of pleurisy. All the patients had symptoms before or at the time of diagnosis except 6 who developed them after diagnosis. Table 1 lists the symptoms and the number of patients in whom they were present. These symptoms may also be classified according to the body system involved. Pulmonary symptoms comprised 44 per cent, con-

stitutional or general symptoms, 36 per cent, pleural symptoms 12 per cent, gastrointestinal symptoms 4 per cent, and laryngeal, bone and joint, nervous system, genitourinary, nasopharyngeal and lymphatic system each 1 per cent or less

The statement has often been made that minimal tuberculosis is asymptomatic. This study significantly shows that the great majority of these patients

do have symptoms. Practically all the symptoms in our patients were unquestionably associated with the tuberculosis. It may be argued that sanatorium patients are symptom-conscious. We believe that complaints actually exist, and a careful history and close questioning of the patients will verify this fact. Frequently only after a diagnosis has been made by routine roentgenography does the patient realize that he has symptoms. This is because the symptoms are not often those of a startling character, such as hemoptysis, blood-streaking of the sputum or pleural pain, but instead are those not arresting in nature, such as cough, — usually explained as due to cigarettes, — fatigue or slight loss of weight. The patients usually consider these of minor importance. These beliefs are substantiated by the experience in the 91 patients in whom a diagnosis was made by routine examination (90 by x-ray and 1 by fluoroscopy), 55 (60 per cent) of whom had symptoms. Abeles and Pinner⁷ observed 91 patients whose tuberculosis was accidentally discovered on routine examination. Of this group, 28 cases were minimal, and 89 per cent of these patients had had symptoms at some time.

Certain symptoms are particularly frequent in minimal tuberculosis. Unfortunately, however, these are not characteristic or specific for this disease alone. They may be present in nontuberculous lung or pleural lesions or even in nonpulmonary conditions. Symptoms in themselves, therefore, cannot serve as the sole criterion for the diagnosis of tuberculosis, but when present they should

definitely suggest the disease, and the diagnosis can then be made only by following through with a chest x-ray examination.

Besides contact and routine examinations, the only factor that aided early diagnosis in this series was an acute onset or hemoptysis that prompted an immediate medical checkup. On the other hand, delays in diagnosis were seen because of noncooperativeness in the patients. This was usually due to their failure to seek medical advice early, but occasionally a contact neglected to undergo the examination recommended by the physician. There is much need for education of the public to consult physicians early regarding symptoms. The importance of the symptoms should be stressed, especially those that are not striking in character, which have too often been considered trivial.

In 21 patients a diagnosis of tuberculosis was not suspected or made at the first medical consultation or examination. If the 91 patients diagnosed routinely are not considered, this means that 21 of 109 patients (19 per cent) were missed. The mistaken diagnoses included the following conditions: pneumonia, 3 cases, pleurisy, 3 cases, asthma, 3 cases, "cold," tonsillitis, and dyspepsia and colitis, 2 cases each, and influenza, sinusitis, nephritis, rheumatic heart disease, arthritis and unexplained fever, 1 case each.

Almost 75 per cent of the errors were in diagnoses of nontuberculous respiratory or upper respiratory conditions. To prevent these errors, it should be a routine practice not to make a diagnosis of pneumonia, bronchitis, asthma, pleurisy, chest cold, catarrhal fever or grippe without first considering the possibility of tuberculosis. The symptoms and physical findings in these cases may be the same as those encountered in tuberculosis. To determine definitely the presence of tuberculosis an x-ray and sputum examination and occasionally a tuberculin test are requisite for all these patients. This would not be an impractical or uneconomical procedure, for the yield of active cases of tuberculosis would be considerable.

The most valuable diagnostic physical finding in tuberculosis is the presence of rales. Changes in fremitus, dullness and breath sounds are not significant enough to be considered. Only 57 (29 per cent) of these 200 minimal cases had rales. This shows how unreliable a physical examination is in the early diagnosis of tuberculosis. A lack of physical signs cannot rule out the disease, for in minimal tuberculosis a normal physical examination is usual.

In 156 patients no tubercle bacilli were recovered, in 3 the records contained no reports, the patients having left the sanatorium before examinations could be made, and in 41 tubercle bacilli were found. They were reported either in smears of the sputum or gastric-contents concentrates or in cultures or both. The demonstration of tubercle bacilli is,

THE EARLY DIAGNOSIS OF MINIMAL PULMONARY TUBERCULOSIS*

radiography, even when carefully done by trained persons. Published studies of fluoroscopy and roentgenographic checkups show that in the hands of experts errors vary from 13 to 35 per cent. The highest number of errors occur in minimal cases, especially those with apical or supraclavicular lesions. Fluoroscopy is especially difficult in obese, thick-chested patients. From the viewpoint of economy, it actually does not cost much less than x-ray examination if allowance is made for the physician's time required for eye adaptation examination, discussion and a report of the case. Moreover, the cost of missed cases is greater than the cost of x-ray examination.

Bloch and Tucker¹¹ have affirmed the value of fluoroscopy. They found tuberculous lesions of the reinfection type in 41 per cent of 15,000 clinic patients. Of these cases, 14 per cent were clinically significant and 58.6 per cent were minimal. These authors stress the following points. The fluoroscope is easy and economical to operate and is extremely adaptable to the practicing physician's office. Its routine use would be a significant diagnostic contribution. It has additional value because an ordinary film may miss a lesion hidden by the scapula, clavicle, ribs or heart, whereas with the fluoroscope the patient can be rotated and the clavicles elevated or depressed.

Daniels¹² emphasizes that the physician in general practice can be an extremely valuable case-finding agent, and considers the large group of patients that come to physicians' offices a fertile field for mass surveys. He estimates that 30 per cent of the general population visit a physician at some time during the year. He reports a study wherein every patient entering his office, irrespective of the complaint, was fluoroscoped and x-ray photographs were taken of all chests with suspicious lesions. In 250 patients, 7 active cases of pulmonary tuberculosis were found. Of these patients, none had a history of contact, 4 had positive sputums, 6 had no physical findings, 3 had an increased sedimentation rate, and 5 had no history indicating pulmonary disease. Daniels admits the errors of fluoroscopy, and advocates having an x-ray miniature-film machine available in each locality for examining all patients visiting private physicians. Fluoroscopy is of definite value and is much better than a physical examination for the discovery of minimal cases, but it is imperfect and cannot be relied on solely for diagnosis. To be certain of the presence or absence of tuberculosis, it would be necessary to x-ray patients considered negative on fluoroscopy.

X-ray examination was the main method employed in diagnosis, having been used in 187 (94 per cent) of the 200 cases in this series prior to admission to the sanatorium. In 97 of these, the film was utilized in a corroborative manner to determine the presence of tuberculosis suspected because of other factors — symptoms, physical

findings and so forth. In 90 cases, the examination was routine consisting of a contact examination, survey, pre-employment investigation or a Selective Service checkup and the diagnosis was made in persons apparently healthy.

The main problem in the control of tuberculosis is that of early diagnosis. In addition, treatment that is necessary should be provided without delay, either in the home, if the conditions there are suitable, or in an institution. The physician has the duty to educate the patient and his family in the infectiousness of the disease and to convince them of the value and necessity of immediate care. A patient may delay proper attention at home, postpone seeking admission to the sanatorium or continue to work after the diagnosis because necessary home adjustments, such as adequate living arrangements, placement of children, payment of rent, purchase of food and clothing, storage of furniture, contact examinations and family medical care, have not been made. To meet these situations requires the co-operation of public or voluntary social-service and welfare associations and of public-health nursing and medical groups. If such problems are taken care of, patients will be prompted to accept medical treatment as soon as the diagnosis has been made. The possibility of progression of the disease can then be avoided and the morbidity and mortality of advanced tuberculosis thereby avoided.

COMMENT

This study has shown that the most important and reliable instrument in the early diagnosis of minimal tuberculosis is x-ray examination. Certainly in over 99 per cent of minimal cases it can effect the diagnosis, often long before other clinical or laboratory findings have indicated the disease. No lung examination can be considered complete without an x-ray examination, and a patient should never be told that tuberculosis is absent unless one has been done. This procedure should be employed in every patient with any symptoms suggestive of tuberculosis, in any illness that tuberculosis may simulate and periodically in all contact cases. Minimal tuberculosis is a symptomatic disease, but to diagnose all persons, including those in an asymptomatic phase, routine mass x-ray surveys are necessary.

Ninety-one (46 per cent) of the patients in this series were diagnosed on a routine examination, — 90 by x-ray and 1 by fluoroscopy — indicating the value of routine investigation. These were apparently healthy persons unsuspected of having an illness, in whom the tuberculosis was accidentally discovered through x-ray examination. Without this fortuitous circumstance, many patients would no doubt have eventually been diagnosed as advanced cases. That routine x-ray surveys find active minimal lesions is an established fact. Of

of course, absolute proof of tuberculosis, but the presence of a negative sputum does not mean that tuberculosis is absent. This is particularly true in minimal cases, as illustrated by the small percentage in this series without positive sputums. A more liberal use of cultures and utilization of guinea-pig inoculations would, however, have yielded a higher percentage of positive reports.

There are several important facts relative to the finding of tubercle bacilli. The number of positive reports depends on the frequency and manner of examination. A single sputum, if negative, is of no value in the diagnosis of tuberculosis. The longer the time used for the collection of sputum, the higher is the incidence of a positive sputum. The use of sputum concentrates alone is not satisfactory; fasting gastric contents must also be examined. This is essential whenever sputum concentrates are negative or there is little or no expectoration. Especially in minimal cases, little sputum may be raised or, as often occurs, the sputum may be swallowed. Sputums or gastric contents that are negative on concentration should be cultured, for many will thus be found to be positive. Moreover, repeated examinations are necessary for proper conclusions about the presence of tubercle bacilli. Should the findings still be negative and tuberculosis be suspected, guinea-pig inoculations of the sputum and gastric contents are required. The ascending order of sensitivity of the methods used in finding tubercle bacilli is as follows: direct smear, 24-hour sputum concentrate, 72-hour sputum concentrate, fasting gastric-contents concentrate, culture of sputum or gastric contents and guinea-pig inoculations. The comparison of the sensitivity of these tests has been described.^{8, 9} In the 41 cases in which tubercle bacilli were found, 10 (24 per cent) were positive with sputum or gastric cultures alone, 9 (22 per cent) with gastric concentrates alone, and 4 with gastric concentrates combined with sputum and gastric-contents cultures. In other words, in 56 per cent of the patients with tubercle bacilli, they were revealed because of the examination of gastric contents and the utilization of cultures. Decker, Ordway and Medlar⁹ report that the repeated use of cultures and guinea-pig inoculations of sputum and gastric contents disclosed bacilli in 70 per cent of active minimal cases.

It is not meant by this discussion that it is necessary to wait for a positive sputum to make a diagnosis of minimal tuberculosis, since an early x-ray examination will indicate the disease. Needless to say, in a case with a purulent sputum persistently negative for tubercle bacilli, tuberculosis is undoubtedly not present.

Other laboratory findings were of little help in diagnosis. The white-cell count was of negligible value. On admission to the sanatorium 148 patients had a count under 10,000, 25 had counts between 10,000 and 15,000, and only 1 patient had a count

of more than 15,000. In 26 cases no count was available.

The sedimentation rate, although more sensitive than the white-cell count, was not diagnostic or indicative of clinical activity. Of the 200 patients, 89 (45 per cent) had a sedimentation rate of less than 10 mm in one hour (Cutler method), 42 patients had a rate of 11 to 15 mm, 29 had a rate between 16 and 20 mm, and 40 had a rate over 21 mm, with all but 2 of these under 30 mm. Thus, 111 (56 per cent) of the patients had a sedimentation rate of over 10 mm.

The tuberculin test was apparently not used in the diagnosis of any patient, but it is possible that in some cases the procedure was carried out without being recorded.

A positive tuberculin reaction means only that a tuberculous infection has taken place in the body, with hypersensitivity to tuberculo-protein present. It provides no definite answer about the type, extent or activity of the disease. A negative reaction may occur in the presence of tuberculosis under special circumstances — if the test is done shortly after infection has taken place and before the tissues have become hypersensitive, in terminal tuberculous disease, in patients with healed tuberculous lesions, in intercurrent acute infections and in aged and debilitated persons. The percentage of reactors is also qualified by the amount of tuberculin, for the larger the dose the greater the number of positive cases. A maximum final dose of 10 mg is required for definite conclusions, since a negative reaction with so much tuberculin usually rules out tuberculosis. The test is especially significant in infants and young children, for if the reaction is positive, it constitutes strong evidence of active tuberculous disease. Rechecking a negative case periodically sometimes shows a positive reaction, thus indicating the occurrence of tuberculous infection. The important point is that the tuberculin test used alone for diagnostic purposes misses many minimal cases, particularly in adults, and that x-ray examination is essential to make the diagnosis.

Fluoroscopy was recorded in 8 cases (4 per cent). In 7 of these it served as a corroborative measure in suspected cases of tuberculosis, and in 1 case it formed a routine examination in an apparently healthy person. This figure is probably not a true indication of the use of the fluoroscope in diagnosis, since the patients no doubt were not specifically questioned about it.

There have been divergent opinions concerning the value of fluoroscopy as a method of early diagnosis. Garland¹⁰ has emphasized the following limitations of this procedure. Its efficiency depends to a moderate degree on the technical factors, and to a high degree on the time taken by the examiner to get his eyes accommodated to the fluoroscope. There is much variation in the visual acuity of physicians. Fluoroscopy is much less accurate than

radiography, even when carefully done by trained persons. Published studies of fluoroscopy and roentgenographic checkups show that in the hands of experts errors vary from 13 to 35 per cent. The highest number of errors occur in minimal cases, especially those with apical or supraclavicular lesions. Fluoroscopy is especially difficult in obese, thick-chested patients. From the viewpoint of economy, it actually does not cost much less than x-ray examination if allowance is made for the physician's time required for eye adaptation, examination, discussion and a report of the case. Moreover, the cost of missed cases is greater than the cost of x-ray examination.

Bloch and Tucker¹¹ have affirmed the value of fluoroscopy. They found tuberculous lesions of the reinfection type in 41 per cent of 15 000 clinic patients. Of these cases, 14 per cent were clinically significant and 58.6 per cent were minimal. These authors stress the following points. The fluoroscope is easy and economical to operate and is extremely adaptable to the practicing physician's office. Its routine use would be a significant diagnostic contribution. It has additional value because an ordinary film may miss a lesion hidden by the scapula, clavicle, ribs or heart, whereas with the fluoroscope the patient can be rotated and the clavicles elevated or depressed.

Daniels¹² emphasizes that the physician in general practice can be an extremely valuable case-finding agent, and considers the large group of patients that come to physicians' offices a fertile field for mass surveys. He estimates that 30 per cent of the general population visit a physician at some time during the year. These were apparently healthy persons unsuspected of having an illness, in whom the tuberculosis was accidentally discovered through x-ray examination. Without this fortuitous circumstance, many patients would no doubt have eventually been diagnosed as advanced cases. That routine x-ray surveys find active minimal lesions is an established fact. Of

these 91 patients, 55 had symptoms, 21 were shown to be positive for tubercle bacilli, and 38, including 14 with progression, showed x-ray changes

The greatest advance in tuberculosis in recent years has been the lesson taught by the mass x-ray surveys. These surveys, applied to Selective Service applicants, to the industrial population, to those to be employed, to those admitted to general hospitals and so forth, have found evidences of clinically significant pulmonary tuberculosis of reinfection type in at least 1 per cent of the cases. Most important is the fact that 65 per cent of the cases have been diagnosed in a minimal stage. The statistics of the surveys indicate that there are many hundreds of thousands of unrecognized and unsuspected cases of tuberculosis in the country that can be detected by routine x-ray examinations. Moreover, rapid, simple, economical and diagnostically accurate methods have been developed, through the use of 14-by-17-inch paper films and 4-by-5-inch and 35-mm — and recently 70-mm — miniature films taken with photofluorographic technic. The routine use of x-ray examination is not an impractical ideal but an absolute necessity and a judicious economy. There is a much greater cost — to the patient, his family and the public — in a missed or delayed diagnosis of tuberculosis than in the expenditure for films that reveal no lesions. It is hoped that in the near future the means will be found to arrange for routine and periodic radiographic examinations of the entire population of the country. When this is done, a great step forward will have been taken in the early diagnosis and eradication of tuberculosis.

SUMMARY AND CONCLUSIONS

The advantages of the early diagnosis of minimal tuberculosis are enumerated.

To determine the factors that could aid early diagnosis, 200 cases with minimal lesions have been studied and the results reported.

Tuberculosis should be suspected at any age, in any occupation and with any type of social or economic background.

Positive contact is not a clear diagnostic indication and was present in only 34 per cent of the patients. Close observation is, however, necessary for contact cases, since the incidence of tuberculous infection among them is high.

Minimal tuberculosis is a symptomatic disease. Eighty-two per cent of these patients had symptoms. This is contrary to the oft-repeated statement that minimal tuberculosis is asymptomatic. The complaints usual in tuberculosis are either acute or

not arresting. The public should be taught the importance of symptoms.

Minimal tuberculosis can masquerade as one of many other ordinary illnesses.

Physical findings are totally unreliable in diagnosis. Only 29 per cent of the patients in this series had rales.

Tubercle bacilli were found in 21 per cent of the cases. The percentage of positive reports depends on the type and number of examinations. Sputum smears alone are of very little value. Concentrates and cultures — and ideally guinea-pig inoculations — of sputum and fasting gastric contents are required for an adequate search for tubercle bacilli.

The white-cell count and sedimentation rate are of little diagnostic help.

The tuberculin test received almost no use in the diagnosis of these cases.

Fluoroscopy has its value but is an imperfect diagnostic method.

The vital role of the practicing physician as a tuberculosis case-finding agent has been indicated.

Prompt acceptance by patients of medical treatment is essential.

X-ray examination was used for diagnosis in 94 per cent of the cases before admission. This is the only reliable method for early diagnosis of minimal tuberculosis. Films should be taken in every case with symptoms suggestive of tuberculosis, in any illness that may be tuberculosis and periodically in all contact cases. Routine radiographic examinations are required for the entire population. The value of mass x-ray surveys has been demonstrated.

PENTOTHAL SODIUM ANESTHESIA IN NEUROLOGIC SURGERY

EDWARD W. SHANNON, M.D.,* AND W. JAMES GARDNER, M.D.†

CLEVELAND, OHIO

THE purpose of this article is to summarize our experience with Pentothal Sodium anesthesia in neurologic surgery. Since this kind of anesthesia was first used in this clinic for pneumoencephalography,¹ its use has been extended to include all

PREOPERATIVE PREPARATION

The night before operation a cleansing enema and 0.1 gm of Seconal Sodium are given. The meal before operation is omitted and 0.1 gm of

neurosurgical procedures, regardless of length, in patients over ten years of age.² Although this report is based on a planned study of 101 unselected cases in which Pentothal Sodium was the anesthetic agent, we have employed it in several hundred additional major neurosurgical procedures. No death could be attributed to the anesthetic.

The types of operation are listed in Table 1, as well as the age incidence, the duration of the anesthesia and the dosages of Pentothal Sodium.

*Fellow in neurosurgery, Cleveland Clinic.

†Neurosurgeon-in-chief, Cleveland Clinic.

Seconal Sodium is given two hours before operation. Forty-five minutes before operation adults receive 0.65 mg of atropine and children a proportionately smaller dose. When the patient is extremely nervous or upset, morphine is given with the atropine.

After the patient has been placed in position and the operative site has been prepared, a suitable vein in the hand or forearm is selected for the intravenous administration of 5 per cent dextrose in saline solution. A three-way stopcock is interposed between the intravenous needle and the dextrose solution. Rubber tubing leads from the stopcock to a 20-cc syringe containing the Pento-

thal Sodium For the last few years we have used nothing but a 2.5 per cent solution of this anesthetic agent

After the patient has been anesthetized and draped, the line of the incision is thoroughly infiltrated with 1 per cent novocain solution and the operation is begun. A Geudel airway is usually placed in the patient's mouth for the administration of oxygen if necessary

OPERATIVE PROCEDURES AND RESULTS

Subtentorial Craniotomy

In our experience, Pentothal Sodium anesthesia has been superior to all others for craniotomies. Because the induction of anesthesia is brief, the patient is under an anesthetic for a shorter time than would be the case if inhalation anesthesia were used. Moreover, since with this anesthetic agent there is no increased intracranial pressure, bleeding is reduced. If used together with local anesthesia, the Pentothal Sodium anesthesia need not be deep and may be lightened after the scalp flap has been reflected. During closure of the scalp wound, the anesthetic may again be deepened if necessary. When the patient is returned to bed, his head is elevated 45 cm. to lower the venous pressure and reduce postoperative oozing. Postoperative vomiting and retching, which are frequent after inhalation anesthesia, cause severe fluctuation in intracranial pressure and increase the tendency to postoperative bleeding. After Pentothal Sodium anesthesia vomiting is an unusual occurrence.

In suspected brain tumors encephalography is frequently employed as a diagnostic procedure. The encephalogram is made in the operating room, and craniotomy is performed immediately after the roentgenograms have been made. This naturally increases the duration of the anesthesia. In 3 sample cases the relative quantities of 2.5 per cent Pentothal Sodium used for pneumoencephalography and craniotomy were as follows: Case 1, 33 and 65 cc., Case 2, 25 and 90 cc., and Case 3, 35 and 60 cc.

That 2 patients in this series of thirty craniotomies required larger than average quantities was attributed to their excessive use of alcohol and tobacco. This is usually true of this type of patient. There were no untoward reactions to the drug in any of these cases.

Suboccipital Craniotomy

There were 11 suboccipital craniotomies in this series. Pentothal Sodium anesthesia was found to have the same advantages for this type of operation as for supratentorial craniotomies. In addition,

the patient is able to co-operate in securing the proper position for operation. This is of great importance because the patient is placed in the sitting position for this operation. In this series the only complication was respiratory obstruction in an extremely obese patient, which was relieved by changing the position of the head.

Other Operations

Section of the sensory root of the fifth nerve in the middle fossa was done in 21 cases. The patient is not anesthetized until after the skin is prepared and the field draped. As soon as the sensory root is sectioned, the anesthetic is discontinued, denervation making the closure painless. Because many of these patients are aged and are poor surgical risks, a short anesthetic is of distinct advantage. There were no untoward reactions in this group.

Lumbar laminectomy for protruded intervertebral disk was done in 10 cases. Pentothal Sodium anesthesia has the disadvantage in this procedure of allowing little muscular relaxation. Accordingly, during the last nine months the operation has been done under spinal anesthesia, supplemented with Pentothal Sodium if the patient is very apprehensive or if the spinal anesthetic wears off before the operation has been completed. There were no reactions in this group.

Dorsal sympathectomy was performed in 6 cases. All the operations were performed with the patient in the sitting position. There were no reactions to the anesthetic.

Laminectomy was performed in 6 cases, either for cord tumor or for protruding intervertebral cervical disk. The only untoward reaction was labored respiration, which was relieved by changing the patient's position.

A patient who suffered from a traumatic head wound had continuous generalized convulsive seizures until 5 cc. of a 2.5 per cent solution of Pentothal Sodium was given. A patient who was being trephined for subdural hematoma developed hiccup and laryngeal spasm, which lasted for ten minutes. When the anesthesia was gradually deepened, both reactions stopped, and the patient's condition remained good for the rest of the procedure.

SUMMARY

Intravenous Pentothal Sodium anesthesia has been found to be extremely satisfactory and safe for neurologic surgery.

CLINICAL NOTE

AGRANULOCYTOSIS FOLLOWING
MAPHARSEN THERAPY

A REPORT OF

TWO CASES TREATED WITH PENICILLIN

CAPTAIN JOHN F McMANUS, MC, AUS*

AGRANULOCYTOSIS following Mapharsen therapy for syphilis has been a serious but fortunately rare occurrence. The concurrent use of penicillin in the treatment of this complication and of syphilis has not been previously reported. Hence, the following case reports are of interest.

CASE 1. A 21-year-old Negro soldier developed a penile ulcer on May 23, 1944. *Treponema pallidum* was demonstrated in a dark-field examination on May 27. The Kahn reaction was negative on May 30. The past history was negative except for gonorrhea in September, 1943, which had been successfully treated with sulfonamides.

Except for the presence of a penile ulcer in the coronal sulcus, the physical examination on admission was essentially negative. The weight was 145 pounds. The blood pressure was 100/60.

Intensive therapy was begun on May 30 and consisted of the daily intravenous injection of 0.066 gm of Mapharsen and the intramuscular injection of 0.2 gm of bismuth subsalicylate in oil every 3 days. A mild Herxheimer reaction followed the first injection of Mapharsen. Treatment was given for 8 days without other adverse reactions. On the 9th day, the patient manifested a moderately severe Milhan reaction, and arsenotherapy was omitted for 5 days. Arsenotherapy was resumed on the 14th day, when 0.030 gm of Mapharsen was given. This was followed by a rise in tem-

On the 22nd day, anorexia was more marked and the patient complained of pain and swelling in the region of the left submaxillary lymph nodes. On physical examination he did not appear to be in distress. There was moderate redness and puffiness of the gums, and slight injection of the pharynx. The left submaxillary lymph nodes were tender and slightly swollen. During that day the patient did not feel especially ill and had to be forced to remain in bed. The temperature fluctuated between 102 and 103°F and the maximal pulse was 96. The white-cell count was 3200 with no granulocytes. Treatment on the 22nd and 23rd days consisted of four daily intramuscular injections of 100 mg of B A L in oil. On the 23rd day, the temperature remained elevated and reached a maximum of 103°F, the pulse rose to 112. By that time, the patient looked acutely ill and complained of weakness and nausea. The other signs and symptoms had progressively increased. The white-cell count was 4600, with 1 per cent nonsegmented neutrophils. On the 24th day, the weakness had increased and prostration was marked. It became increasingly difficult for the patient to open his mouth because of the pain and swelling of the left submaxillary lymph nodes. Examination of the mouth and pharynx was essentially the same as previously noted. Neither ulceration nor necrosis was seen. Treatment on that day consisted of the intravenous injection of 1500 cc of 10 per cent glucose in saline solution, in addition to two injections of 100 mg of B A L in oil. The white-cell count was 3300, with no polymorphonuclear leukocytes. In the evening the prostration had increased and the patient appeared critically ill. The temperature was 103°F, and the pulse 112. Forty thousand units of penicillin was given intramuscularly, and repeated every 3 hours for 7½ days.

On the 25th day, there was a decrease in the pain and swelling of the left submaxillary lymph nodes, and prostration was less evident. The maximum temperature was 102°F. In addition to penicillin, the patient was given two intramuscular injections of 100 mg of B A L in oil and a transfusion of 500 cc of citrated blood. The white-cell count prior to the transfusion was 3900, with 2 per cent segmented neutrophils and 2 per cent eosinophils. On the 26th day, improvement continued and the maximum temperature was 101.6°F. The white-cell count on the following day was 4000, with 3 per cent segmented neutrophils, 13 per cent nonsegmented neutrophils, 2 per cent eosinophils and 32 per cent juvenile forms. The highest temperature reached on the two succeeding days was 99.8°F, and the dramatic

perature to 104.0°F. On the following day the patient was feeling well, and 0.030 gm of Mapharsen was given without any adverse reaction. For the next 6 days, full doses of Mapharsen were given, — 0.066 gm a day, — without any apparent ill effect. On June 19, the 21st day, the white-cell count was 3200, with 2 per cent neutrophils. That evening the patient complained only of slight anorexia. The temperature rose to 100.6°F and the pulse to 80. Thereafter, no more arsenic or bismuth was given. A quantitative blood Kahn reaction had been positive (10 units) on the 13th day. In 21 days of therapy the patient had received sixteen injections of Mapharsen, totaling 0.984 gm, and seven injections of bismuth subsalicylate, totaling 1.4 gm.

clinical improvement that followed paralleled the improvement in the blood picture.

After the 28th day, the patient was afebrile and asymptomatic except for slight, decreasing weakness. Penicillin therapy was completed on the 32nd day. By the 37th day the penile ulcer had healed, physical examination was essentially negative, and the Kahn reaction was negative. The patient was discharged to duty on the 39th day.

In the treatment of the agranulocytosis the patient had received 1200 mg of B A L in oil, 500 cc of citrated blood and 2,400,000 units of penicillin (Table 1).

CASE 2. A 23-year-old soldier developed a penile ulcer on August 4, 1944. *T. pallidum* was demonstrated in a dark-field examination on August 17. The qualitative Kahn reaction was positive on that day, and a quantitative test was positive (80 units) on August 22. The past history in-

thal Sodium For the last few years we have used nothing but a 2.5 per cent solution of this anesthetic agent

After the patient has been anesthetized and draped, the line of the incision is thoroughly infiltrated with 1 per cent novocain solution and the operation is begun. A Geudel airway is usually placed in the patient's mouth for the administration of oxygen if necessary

OPERATIVE PROCEDURES AND RESULTS

Subtentorial Craniotomy

In our experience, Pentothal Sodium anesthesia has been superior to all others for craniotomies. Because the induction of anesthesia is brief, the patient is under an anesthetic for a shorter time than would be the case if inhalation anesthesia were used. Moreover, since with this anesthetic agent there is no increased intracranial pressure, bleeding is reduced. If used together with local anesthesia, the Pentothal Sodium anesthesia need not be deep and may be lightened after the scalp flap has been reflected. During closure of the scalp wound, the anesthetic may again be deepened if necessary. When the patient is returned to bed, his head is elevated 45 cm. to lower the venous pressure and reduce postoperative oozing. Postoperative vomiting and retching, which are frequent after inhalation anesthesia, cause severe fluctuation in intracranial pressure and increase the tendency to postoperative bleeding. After Pentothal Sodium anesthesia vomiting is an unusual occurrence.

In suspected brain tumors encephalography is frequently employed as a diagnostic procedure. The encephalogram is made in the operating room, and craniotomy is performed immediately after the roentgenograms have been made. This naturally increases the duration of the anesthesia. In 3 sample cases the relative quantities of 2.5 per cent Pentothal Sodium used for pneumoencephalography and craniotomy were as follows: Case 1, 33 and 65 cc.; Case 2, 25 and 90 cc.; and Case 3, 35 and 60 cc.

That 2 patients in this series of thirty craniotomies required larger than average quantities was attributed to their excessive use of alcohol and tobacco. This is usually true of this type of patient. There were no untoward reactions to the drug in any of these cases.

Suboccipital Craniotomy

There were 11 suboccipital craniotomies in this series. Pentothal Sodium anesthesia was found to have the same advantages for this type of operation as for supratentorial craniotomies. In addition,

the patient is able to co-operate in securing the proper position for operation. This is of great importance because the patient is placed in the sitting position for this operation. In this series the only complication was respiratory obstruction in an extremely obese patient, which was relieved by changing the position of the head.

Other Operations

Section of the sensory root of the fifth nerve in the middle fossa was done in 21 cases. The patient is not anesthetized until after the skin is prepared and the field draped. As soon as the sensory root is sectioned, the anesthetic is discontinued, denervation making the closure painless. Because many of these patients are aged and are poor surgical risks, a short anesthetic is of distinct advantage. There were no untoward reactions in this group.

Lumbar laminectomy for protruded intervertebral disk was done in 10 cases. Pentothal Sodium anesthesia has the disadvantage in this procedure of allowing little muscular relaxation. Accordingly, during the last nine months the operation has been done under spinal anesthesia, supplemented with Pentothal Sodium if the patient is very apprehensive or if the spinal anesthetic wears off before the operation has been completed. There were no reactions in this group.

Dorsal sympathectomy was performed in 6 cases. All the operations were performed with the patient in the sitting position. There were no reactions to the anesthetic.

Laminectomy was performed in 6 cases, either for cord tumor or for protruding intervertebral cervical disk. The only untoward reaction was labored respiration, which was relieved by changing the patient's position.

A patient who suffered from a traumatic head wound had continuous generalized convulsive seizures until 5 cc. of a 2.5 per cent solution of Pentothal Sodium was given. A patient who was being trephined for subdural hematoma developed hiccup and laryngeal spasm, which lasted for ten minutes. When the anesthesia was gradually deepened, both reactions stopped, and the patient's condition remained good for the rest of the procedure.

SUMMARY

Intravenous Pentothal Sodium anesthesia has been found to be extremely satisfactory and safe for neurologic surgery.

tion of toxic drugs, it is of paramount importance to discontinue immediately the use of the drug. Treatment with repeated blood transfusions and the administration of Pentnucleotide, adenine sulfate, liver extract, leukocyte cream and yellow-bone-marrow extract has not been uniformly successful. Many cases have ended fatally because of overwhelming septicemia, in the absence of circulating leukocytes. There have been some cases in which spontaneous recovery occurred. Thus, the control of septicemia is essential to the successful management of patients with agranulocytosis while awaiting the spontaneous or induced recovery of the hematopoietic function of the bone marrow. The sulfonamides have been successfully used in this respect,^{7,10} even when the agranulocytosis has been associated with sulfonamide therapy.¹¹ Agranulocytosis following sulfonamide therapy has been frequently observed, but sulfadiazine is probably the least likely of the sulfonamides to cause serious toxic reactions. On the other hand, fatal granulocytopenia developing during the administration of sulfadiazine has been reported.¹²⁻¹⁴ It has been suggested that penicillin might prove a better preparation for the management of severe infection in patients with agranulocytosis.¹⁵

Cases of agranulocytosis that developed following the use of sulfathiazole in which penicillin was successfully employed have recently been reported.^{16, 17} In 2 cases, agranulocytosis complicating Mapharsen therapy for syphilis has been successfully treated with penicillin, but the amount administered was probably inadequate to eradicate the primary infection.¹⁸

The patient in Case 1 received a total of 1200 mg of BAL in oil by intramuscular injections during the four days after the onset of agranulocytosis. This substance has a double pharmacologic action, first by converting arsenic within the tissues into a nontoxic compound, and second by increasing the elimination of arsenic in the urine. It has been demonstrated that this substance is not toxic in the dosage given and is of distinct value in the treatment of arsenical dermatitis. There was reason to believe that its administration might be of value in other arsenical reactions; hence it was used in Case 1. There was even greater indication for its use in Case 2, because of the coexisting toxic hepatitis, but it was not employed and recovery did not seem to be retarded as a result. But the first patient had received a total of 0.984 gm of Mapharsen prior to the onset of agranulocytosis, whereas the second had received only 0.520 gm. No definite benefit is claimed for its use, however, since the patient receiving it showed neither clinical nor hematologic evidence of improvement until penicillin was given in addition.

The principal reason for using penicillin in these cases was on account of its demonstrated value in the treatment of syphilis. Moreover, there was less risk than in using sulfadiazine, which is capable of producing agranulocytosis. These patients were therefore given penicillin according to the routine that has since been adopted as the one of choice in all patients with primary or secondary syphilis. Sepsis was promptly controlled in both patients, and Case 1 demonstrated a reversal of serologic reaction from positive to negative at the conclusion of treatment. In Case 2, the titer of the Kahn reaction dropped from 80 to 10 units during treatment. It seems probable that this patient has attained seronegativity without further treatment, but this cannot be definitely stated because follow-up serologic reports are not yet available.

SUMMARY

Two cases of acute agranulocytosis — one with coexisting toxic hepatitis — attributable to Mapharsen therapy for syphilis are reported. Penicillin was of distinct value, both in promoting recovery by combating sepsis and in the treatment of the underlying syphilis.

cluded an attack of hepatitis in 1942 following vaccination for yellow fever. The patient was a periodically heavy drinker of alcohol.

Except for the presence of two ulcers on the shaft of the penis and bilaterally enlarged inguinal lymph nodes, physical examination was essentially negative. The weight was 150 pounds. The blood pressure was 120/80.

Intensive therapy was begun on August 18, and consisted of daily intravenous injections of 0.065 gm. of Mapharsen and intramuscular injections of 0.2 gm. of bismuth subsalicylate in oil every 3 days. A mild Herxheimer reaction followed the first injection of Mapharsen. Treatment was given for 8 days without other adverse reactions. On the 9th day, the patient developed a moderately severe Miliar reaction, and treatment with arsenic and bismuth was omitted and permanently discontinued. In eight days of intensive therapy the patient had received eight injections of Mapharsen, totaling 0.520 gm., and three injections of bismuth subsalicylate, totaling 0.6 gm.

Six days after the last injection of Mapharsen, the patient complained of anorexia and appeared slightly jaundiced. Urinalysis revealed a trace of bile. A diagnosis of toxic hepatitis due to Mapharsen was made. The appetite decreased as the jaundice grew more intense during the next several days. The liver became tender and palpable 1 fingerbreadth below the right costal margin in the midclavicular line. A low-grade fever continued until September 8, when the patient complained of a chill in addition to a sore throat and gums. The temperature rose to 104.6°F. Physical examination revealed, in addition to jaundice and an enlarged, tender liver, a moderately increased redness and swelling of the gums and pharynx. No areas of ulceration or necrosis were seen. The white-cell count was 3850, with 9 per cent

therapy was completed on September 15, at which time the quantitative blood Kahn reaction was positive (10 units). Clinical jaundice was not detectable after September 23. The penile ulcers had entirely healed and physical examination was essentially negative on October 3, when the patient was transferred to the rehabilitation section. He remained there for 1 week and was discharged to duty feeling entirely well. The patient received 2,400,000 units of penicillin in the management of the agranulocytosis and of the primary syphilis. No B A L or blood transfusions were given (Table 2).

Agranulocytosis has been recognized as a serious but rare complication following standard Mapharsen therapy for syphilis. Fatalities have been reported by a number of observers.¹⁻⁴ On the other hand, Stephenson, Chambers and Anderson^{5, 6} reported a total of over two hundred and eighty-five thousand injections of Mapharsen with no fatalities due to agranulocytosis. Kasich⁷ quotes Nelson's series of 4066 patients who had received over fifteen thousand injections of Mapharsen, in 2 of whom blood dyscrasias occurred. No cases of agranulocytosis were reported in a series of 4871 patients who had received intensive Mapharsen therapy.⁸ Studies of the sternal bone marrow in 14 patients during intensive arsenotherapy revealed no significant

segmented neutrophils and 3 per cent eosinophils. Penicillin therapy was immediately begun, and the patient was given 40,000 units intramuscularly every 3 hours for the next 7½ days. On September 9, he appeared better and the maximum temperature was 102.8°F. The white-cell count was 4650, with 7 per cent segmented neutrophils, 3 per cent eosinophils and a normal number of platelets.

On the following day improvement continued and the highest temperature was 100.5°F. The white-cell count was 3750, with 2 per cent segmented neutrophils, 1 per cent nonsegmented neutrophils and 4 per cent eosinophils. On September 11, improvement was still more evident and the temperature reached a maximum of 99.4°F. The white-cell count was 7400, with 11 per cent segmented neutrophils and 3 per cent eosinophils. The patient was afebrile on September 12 and remained so thereafter. He had no complaints after that date, and the liver was no longer palpable. The jaundice was still evident, although decreased in intensity. The white-cell count on September 12 was 8800, with 20 per cent segmented neutrophils and 4 per cent nonsegmented neutrophils.

The remainder of the convalescence was uneventful, and the blood picture rapidly returned to normal. Penicillin

effect on either the erythrocytic or the leukocytic series of cells.⁹ Kasich⁷ has reported 2 cases in which agranulocytosis followed standard Mapharsen therapy. The patients recovered following the use of sulfadiazine, but he does not mention any further therapy for syphilis. Kasich recommends frequent white-cell counts for all patients receiving Mapharsen. When intensive arsenotherapy was made the treatment of choice in this theater for patients with primary and secondary syphilis, the routine of making white-cell counts and differential counts at five-day intervals was adopted. Patients in this hospital received a diet low in fats but high in proteins and carbohydrates. No supplementary vitamins or drugs were used.

To promote recovery in patients who have developed agranulocytosis following the administra-

of scientific medical knowledge organized to the purpose of making this knowledge and skill available to those patients who seek its beneficence

The history of medicine is swift of change. Medical knowledge in its scientific aspects has expanded prodigiously through scientific research, to such an extent that those responsible for the curriculum have an impossible task of holding the essentials for medical education in its fullest sense within the nonelastic limits of time allotment. Choices must be made. At the moment it is the science of medicine that has won out. There is danger that medicine will be thought of as synonymous with the scientific aspects of medicine alone, and not be left free to its broader definition, with scientific medicine held in its true relation to the whole subject. Heroic efforts are being made by many of your clinical leaders to combat the crowding out of these social and humanitarian aspects of medicine. Dr Ryle in his definition of social medicine ably analyzes the situation in medicine today. He contends that as clinical medicine resorts more and more to technical procedures there is less and less intimate understanding of the patient as a person. "Science without humanism," he writes, "may work with atoms but it will not work with men." He argues for recognition of the "interdependence of clinical, social and environmental study" of the patient for "the contribution which each can make to a better appreciation of etiology and prognosis and to a better organization" of medical care. He maintains

Social medicine means what it says. It embodies the idea of medicine applied to the service of man as *socius*, as fellow or comrade, with a view to a better understanding and more durable assistance of all his main and contributory troubles which are inimical to active health and not merely to removing or alleviating a present pathology. It embodies also the idea of medicine applied in the service of *societas*, or the community of men, with a view to lowering the incidence of all preventable disease and raising the general level of human fitness.

One of the correctives that has been resorted to in the Boston hospitals is the inclusion in the medical team of the medical social worker, who is charged with responsibility to bring to the clinician's attention information about the patient as a person in his social setting. Her purpose is to bring into clearer focus the meaning of illness to the patient — its effect on his usual way of life, his responsibilities and unfulfilled family obligations. It is out of such experience as a medical social worker that I speak to you today.

It is *not* the function of the medical social worker to take over all the social responsibility for care of the patient. The patient is the responsibility of the physician. The more aware the latter is of the significance of social factors in the patient's life as they may bear on his illness, the more readily will he make suitable use of the assistance of the social worker. He turns to her to elaborate the brief — too brief — social study of the patient and

to assist him and the patient in working out a practical plan supportive of his medical-care plan.

What are some of the methods of securing pertinent social information? One principle we must accept is that of *individualizing* the patient. For the patient this is entirely acceptable. The patient feels unique — he *is* unique. We can lose ourselves in the group in some situations, — ball games or symphony concerts, — but in illness we are unique. The feeling of the patient about his illness — its meaning to him — is then of first importance.

The trained medical social worker disciplined by working closely with expert clinicians has special reason to appreciate some scientific procedures and principles. She is trained to case study in the area of the social life. She keeps in mind the common need for a normal, satisfactory way of life — namely, satisfying family relations, health, economic independence with good occupational adjustments, freedom in recreational activities and a reasonable degree of fulfillment of one's wishes and interests. The patient's so-called "social situation" prior to illness and as effected by illness is of concern to the medical social worker. She must determine what aspects of this situation may be significant to the physician. The gathering of such data from the patient, his family and others, the correlation of them to the clinical findings in conference with the physician, and planning with the patient and the physician to make available to the patient her experience and resourcefulness are her suitable functions.

I think of the Greek chef who was sent into the hospital ward for study of gastric ulcer. After a few days there, he insisted in broken English that he must go home. A period of three or four weeks of carefully regulated regimen under observation on the ward was advised. The reasons for his resistance to the medical plan were brought to light when his Greek physician and a Greek priest were brought into consultation with the physician in the wards. There was the patient's fear of operation, but chiefly there was his anxiety about the welfare of his wife and three children. After the ward physician's careful explanation of the reason for the hospital stay had been interpreted to him and his wife, and he had received reassurance that his job in a Greek restaurant would be held for him, he calmly accepted the medical plan.

History-taking in medical experience as practiced in our busy wards is almost entirely concerned with the restricted medical situation. The social history is meager and often inadequate. The patient, a highly valuable source of information, may not give the full story. I will give you a case in point that illustrates the nature of social evidence.

A girl of sixteen with ulcerative colitis was admitted to the ward for study and treatment. The original social data on the medical record under "Family History" stated that the mother had died

SYMPOSIUM ON MEDICAL SOCIOLOGY

SOME CLINICAL ASPECTS OF SOCIAL MEDICINE*

IDA M. CANNON†

BOSTON

THE English language sometimes seems to obstruct the processes of thinking. Words may become impoverished, or they may become so weighted with a variety of meanings that when they reach the auditory equipment of a dozen persons they carry twelve different meanings and so cloud mutual understanding. "Social" is one of those words. It would have been helpful to me in tackling the subject of social medicine if I could have known beforehand what the term "social" as related to medicine means to each of you. One has only to refer to the dictionary to find the reason for some of the confusion in its use, for there are given therein at least eleven varieties and shades of meaning. One synonym is given as "convivial." You may judge whether that is pertinent to our discussion today.

For our purpose we might as well leave it that the term "social" is not definitive. Let us accept it as having to do with human interrelations, and pass on to my contention that the phrase "social medicine" is in a sense ambiguous. We may presume to use the phrase "scientific medicine" if we wish to specify one focus of attention within the broad term "medicine." But what about "social medicine," a common phrase these days, and now dignified by a highly significant development at Oxford in the establishment of a professorship of social medicine? In the *British Medical Journal* for November 20, 1943, Dr. John A. Ryle, who holds that chair, has given an excellent statement of his use of the term in his article, "Social Medicine: Its meaning and scope." I have reason to be deeply interested in his presentation, and I can accept the utility of the phrase at this stage in a rethinking of our concept of medicine.

But before I deal with my assignment of addressing you on the subject of social medicine, I wish to register my reasons for objection to the term as ambiguous. Let us accept the brief dictionary definition of medicine in its broad inclusive meaning as "the science and art of dealing with the prevention, cure and alleviation of disease to man." How, then, can medicine as such be other than social? How can it be divorced from its social, its human and community, significances and still be so defined? Even the research laboratory worker, with his attention focused on the study of the blood,

serves the goal of relief of human ills. We may ask how an education in medicine can be justified if it fails to keep clear the ultimate humanitarian purposes of that education.

My desk at the hospital is so placed that I can readily see the ambulance rushing up to the Emergency Ward at any time of the day. It is a rule of the parking space that there must be no obstacle to the approach to the Emergency Ward entrance, where at any moment, day or night, medical care is immediately available for the patient in emergency need, no matter who he is. There is no moralistic question whether he is "worthy" of medical skill, no question of his economic status. He is a patient. That is enough. Other less important questions may have to be considered later, but the immediate urgent medical need is the clear focus of attention. And why do we so easily take this for granted and assume that there is nothing unique in it? Why all this meticulous care? It is characteristic of thousands of hospitals all over the land, and it is a high tribute to the medical profession that this is so.

Obvious and accepted facilities such as these are so characteristic of our social life that we accept them without due appreciation of their significance. There must be meaning in this devoted attention of doctors and nurses to saving human life. What is the reason? Surely not the mere preservation of biologic existence. How tragic it is when the highest medical and nursing skill leaves the patient nothing but breathing and heartbeat, with little capacity to play his part in his social relations. The essential purposes of physicians, surely the "flower of our civilization," as Stevenson termed them, rest in something more than the saving of life itself. Is it not a tacit recognition of the meaning of life? And the deepest meaning of life for us human beings is in our personal, social relations. Its meaning would be bare if we were stripped of our immediate family and those dearest to us, or if our work and play had no comradeship in friendships made more deeply significant through mutual experiences.

It is in terms of disturbances in these relations that patients bring to the hospital with their diseases that I wish to consider the practice of medicine as you are to see it in your hospital experience. The focus will be on the effects of illness on personal and community life and the more distinctly social aspects of medicine. This focus should not blind us to the broad significance of the hospital as bringing to bear on the patients' problems all the wealth

*This is the first of a series of nine lectures on medical sociology given weekly at Harvard Medical School during January, February and March, 1945. They were sponsored by the Department of Preventive Medicine and were primarily intended for third year students. These articles will temporarily replace the reports "Medical Progress."

†Formerly chief of Social Service, Massachusetts General Hospital.

pathology, with due consideration given to minutiae, is time-consuming and tends to limit the area of attention, to the exclusion of a breadth of view. In the light of the vast realm of medicine, we must accept the necessity for specialization, with its deepening and enriching of knowledge and of skills for merciful purposes. Specialization in the social aspects of medicine has come as a logical development of clinical specialization and the necessary organization of services to large numbers of patients in the present-day institutional practice of medicine. Medical practice deprived of specialized knowledge and skills is superficial indeed. How are the high value of specialization and the delegation of responsibility to be applied to adequate care of the patient? Only, I believe, through mutual respect for specialized knowledge and skills and a clear purpose to strive for unity in diversity.

We are a long way from effective integration in the medical care of our patients. The modern scientifically oriented teaching hospital, for instance, presents a complicated array of specialties within clinical medicine, together with several professional groups to whom special services are delegated. When the purpose of care of the patient is the com-

mon bond within this group, there is an opportunity for a high level of democratic functioning. The physician, the nurse, the medical social worker, the dietitian, the occupational and physical therapists, the librarian and the clergyman must each understand the function of the others and recognize without professional jealousies that there are areas of mutual responsibility. I firmly believe that the physician, who must be the leader of the group, should carry the primary responsibility in as broad a scope as his capacity and time allow, and that he should be the one to co-ordinate the special services that complement and supplement his own care of the patient. Such integration of special skills is not as yet the usual practice in modern hospitals.

The humanities as related to scientific medicine call for intelligent study, as one notes the trends of hospitals toward assumption of broader community-health services. In this trend there is sore need for the leadership of well educated medical men, men to whom education has yielded its most precious gift, open-mindedness and flexibility of thought, with a sensitive awareness of social responsibilities.

of possible heart trouble at thirty-two, that the father was living and had recently been discharged from the Army for "malaria", that there were two brothers—one with possible kidney trouble, and that a sister had died of pneumonia at the age of five

Under "Social History," it was recorded that after the death of the mother, the father found it impossible to work and to care for his daughter. The patient was placed in a boarding school, where she said she was quite happy. Following this, she lived with a foster family for five months and was quite dissatisfied, since these people were allegedly unkind to her. For the last six months she had lived with another foster family, in which she was contented and happy. At the time of the report she was attending junior high school, where she was in the tenth grade.

Social investigation through agencies that had been concerned with the family for many years—among them the Society for Prevention of Cruelty to Children—revealed the following facts. The mother deserted the family when the patient was ten years of age, the father, a seafaring man of low intelligence and uncertain responsibility, was unable to care for the children and gave them up to an institution for destitute children. The five-year-old sister was legally adopted, a favorite brother was later placed in a foster home and the patient lost track of him. In 1942, she was placed in a private semidisciplinary home for girls because of her behavior, and since 1943 she had been placed in two different foster homes in an attempt to meet her obvious need for a home and family life.

The patient's own first report of her history was readily understood to express her desire to create out of her fancy a satisfactory family background. It could have served no good purpose to confront this extremely sick girl with the social evidence at hand, but this evidence served well the clinician and psychiatrist, who through the data given by the patient and the facts secured by the medical social worker were able to estimate the psychic trauma of childhood for this sensitive girl. Just as the dread evidence of cancer is left with the surgeon to disclose in due time to the patient or her family, so the psychiatrist may guard social facts until, having gained the patient's full confidence, he deems it wise to face those facts with her and to help her in achieving a more realistic attitude toward life.

Social factors may be etiologically significant, especially in psychosomatic medicine. Surely there are causal factors in disease to be found in an unwholesome physical environment and in industrial hazards, as well as in lack of decent recreational facilities for youth while alluring evil influences flourish around them. Possibly the term "ecology" may serve the purpose better. I further suggest that diagnosis in its fullest meaning would be more significant if the pathologic entity were placed in

the setting of the adverse social factors. The question is not only what kind of patient has the disease but what difficulties beset him in his social relations. Surely one could get a fairer estimate of prognosis if these factors were taken into account and the social worker could help plan social treatment with the patient, in close collaboration with the physician in his medical-treatment plan.

The importance of the patient's participation in treatment is becoming increasingly significant. The old days of pills and powders have passed. As scientific knowledge progresses, as specific dietaries are recognized as therapeutic and as chronic diseases such as arthritis call for a carefully regulated regimen of rest or specific exercises, the patient must share enhanced responsibility for successful treatment. Obstacles to treatment, whether in the patient's attitude or in his social situation, must be overcome.

Last winter a forty-two-year-old patient came to one of our hospitals from a nearby state for treatment of hypertension. He was found to be an excellent candidate for the Smithwick operation. His medical record contained these notes under "Social History": "Married and five children, living and well. Lost present job for medical reasons, couldn't keep up. Afraid of dizziness."

The patient was referred to the social worker, with a report that he had refused the proposed plan for medical care when it was explained that it would mean a few months at home with diet regimen for weight loss, followed by operation with a carefully guarded and lengthy convalescence. The patient had had an industrial accident in 1937 that resulted in amputation of his leg, but in spite of this handicap he had returned to his skilled work in an aircraft factory. His job as drill-press operator entailed lifting heavy steel bolts and feeding them into the machine. He remained sitting while the machine was in operation, but was forced to stand repeatedly while it was being supplied with bolts.

The patient's return to this job was obviously out of the question. Fortunately, he was a resident of a state in which the revised Physical Rehabilitation Act was in effective operation. The surgeon's plan was offered in definite form, and the way was cleared for it through social planning with the patient, the physical-restoration supervisor and the Welfare Department under provision for Social Security Aid to Dependent Children. Careful following of a diet regimen made possible the operative procedure, and after suitable convalescence a program for vocational training in office work was begun.

It is easy to accept the principle that the patient's personal and social situation should be taken into account in the treatment of his disease. It is not so simple to put this into practice in medical care in our busy, modern hospitals and clinics. Time limitation is a serious factor. Focus of attention on

NORMAL LABORATORY VALUES

To provide ready reference to the normal laboratory values recorded in the "Case Records of the Massachusetts General Hospital" and to the methods used the following tabular summary has been prepared* and is substituted for one of the

cases. A limited number of reprints will be available and will be forwarded, so long as the supply lasts, to readers of the *Journal* on request, provided that an addressed and stamped (1½ cents) return envelope (approximately 4 by 9 inches) is enclosed. All requests should be addressed to Miss Edith E. Parris, Massachusetts General Hospital, Boston 14.

Blood, Plasma or Serum Values

DETERMINATION	MATERIAL ANALYZED	MINIMUM QUANTITY REQUIRED	NORMAL VALUE	METHOD
		cc		
Amino acids (CO ₂ of carboxyl carbon)	Plasma	2	3-4-5 mg per 100 cc	Hamilton and Van Slyke <i>J Biol Chem</i> 150:231, 1943
Amylase	Serum	2	15-35 units per 100 cc	Adapted from Somogyi <i>J Biol Chem</i> 125:399, 1938
Ascorbic acid (vitamin C)	Plasma	0.5	0.4-1.0 mg per 100 cc (fasting)	Butler, Cushman and MacLachlan <i>J Biol Chem</i> 150:453, 1943
Ascorbic acid	White cells	8 (whole blood)	25-40 mg per 100 cc	<i>Ibid</i>
Bilirubin (van den Bergh test)	Serum	2	Direct, 0.4 mg per 100 cc, indirect (total) 0.7 mg per 100 cc	Malloy and Evelyn <i>J Biol Chem</i> 119:481, 1937
Calcium	Serum	2	9.0-10.5 mg per 100 cc †	Fiske and Logan <i>J Biol Chem</i> 93:211, 1931, Folin <i>Lab Manual Biol Chem</i> 5th ed., p. 351
Carbon dioxide (content)	Serum	0.5	26-28 meq per liter ‡	Van Slyke and Neill <i>J Biol Chem</i> 61:523, 1924, Peters and Van Slyke <i>Quant Clin Chem</i> , Vol II (Methods), p. 283
Carotenoids total	Serum	2	100-300 int units per 100 cc	Josephs <i>Bull Johns Hopkins Hosp</i> 65:112, 1939 (modified for photocolorimeter and calibrated with haliver oil of specified vitamin A content)
Vitamin A	Serum	2	40-100 int units per 100 cc	
Chloride	Serum	0.5	100-106 meq per liter	Wilson and Ball <i>J Biol Chem</i> 79:221, 1928
Cholesterol	Serum	0.5	150-230 mg per 100 cc	Bloor <i>J Biol Chem</i> 24:227, 1916

*The chemical data were prepared by G. Margaret Rourke, chief of the Chemical Laboratory, Elsie A. MacLachlan, consultant, and Allan M. Butler, staff physician in charge of the Chemical Laboratory.

†Since the total serum calcium concentration is dependent on the serum protein concentration, evaluation of the significance of a serum calcium value requires a serum protein determination.

‡Values in infants and children may be from 20-26 meq per liter. Milliequivalents per liter equal volumes per cent divided by 2.2. The milliequivalent total CO₂ minus 1.3 is usually about equal to the HCO₃ expressed as milliequivalents per liter. For reason for using milliequivalents as units of concentration here and for other electrolytes see Butler and Talbot *New Eng J Med* 231:20, 1944.

DETERMINATION	AMOUNT ADMINISTERED	MATERIAL ANALYZED	MINIMUM QUANTITY REQUIRED	NORMAL VALUE	METHOD
			cc		
Galactose tolerance	0.5 gm per kg intravenously	Blood	1	Less than 5 mg at 75 min	Basset, Althausen and Coltrin <i>Am J Digest Dis & Nutrition</i> 8:432, 1941
Hippuric acid	1.77 gm sodium benzoate intravenously	Urine	1-hr sample	Greater than 1 gm	Quick, Ottenstein and Weltchek <i>Proc Soc Exper Biol & Med</i> 38:77, 1938, Moser, Rosenak and Hasterlik <i>Am J Digest Dis & Nutrition</i> 9:183, 1942

*The 2-mg method is used in patients with slight jaundice, and the 5-mg method in patients without jaundice, the method is valueless in patients with obvious jaundice

beneath the left fourth, fifth, and sixth ribs anteriorly. This portion of the lung fields, which was near the lateral chest wall, was somewhat obscured by the closely grouped overlying ribs. The remainder of the lung fields did not appear remarkable. The heart was not enlarged but was rounded in the region of the left ventricle. The aorta was tortuous. Another film taken two days later again showed a somewhat triangular-shaped area of increased density against the posterolateral chest wall on the left. A linear area of increased density was present in the left costophrenic angle posterolaterally. There was a hazy area of increased density just to the right of the heart, apparently in the middle lobe.

Soon after admission the patient became markedly orthopneic. After vomiting bloody, bile-tinged fluid, he expired on the fourth hospital day.

DIFFERENTIAL DIAGNOSIS

DR FRANCIS D MOORE This is the story of a man who had had a gall-bladder operation many years before entry and subsequently had a train of events that might or might not have been related to the cholecystectomy. He finally died of what appears, at least on the surface, to have been a third disease.

The history is of the greatest importance in trying to decide the cause of his jaundice. There are a few things not mentioned in the record that would have been a great help in that regard. We read that during the years after the cholecystectomy he had had several attacks of jaundice, each lasting a few days. We should like to know whether there was pain with the jaundice. If a patient has had a cholecystectomy and then postoperatively has bouts of pain and jaundice that pass off spontaneously, one is justified in thinking that a few common-duct stones were left in the duct, which he is passing off one after another, or possibly that he is suffering from that mysterious entity known as "biliary dyskinesia." If the attacks were painless, they were possibly attacks of cholangitis, in which case one would expect fever and possibly chills.

We should also like to know whether there was a long free interval between these postoperative attacks and the train of events that later led up to his last admission. In other words, was there a period of several years when he was free from pain and jaundice? This is important as it would make one feel reasonably confident that retained common-duct stones were not a factor in his fatal illness.

DR RONALD C SNIFFEN I might say in partial answer that Dr E P Hayden saw the patient about four months before the jaundice developed. At that time the patient complained of vague abdominal symptoms. A complete gastrointestinal series was done, but nothing was found.

DR MOORE That tends to make persistent common-duct stones following cholecystectomy less likely.

In his final illness he had a rapid crescendo of pain and jaundice and had itching, a common symptom in extrahepatic biliary obstruction. From that point on, the record tells us of the physical findings and laboratory data in a man with non-inflammatory extrahepatic biliary obstruction, which was incomplete.

My reasons for making these statements are that he had a normal white-cell count and temperature, and it is therefore reasonable to assume that he did not have a primary inflammatory process. The obstruction seems to have been extrahepatic rather than parenchymatous partly because of the high ratio of the direct to the indirect bilirubin, almost 90 per cent, which is quite characteristic of extrahepatic biliary obstruction, and also because with this high total bilirubin there was little evidence of liver-cell damage. The prothrombin time was slightly elevated, it is true, but the albumin-globulin ratio was normal. In other words, the degree of obstruction seems to have been out of proportion to the liver damage.

I do not believe that the obstruction was complete because the patient had bile in his stools, they were brown and showed a chemical test for bile, and just before he died he vomited bile-stained material, which also tells us that the pylorus was patent. We can therefore say that he had incomplete noninflammatory extrahepatic biliary obstruction and, in addition, bleeding into the gastrointestinal tract, since he passed guaiac-positive stools and vomited some blood just before he died. Incomplete extrahepatic obstruction and bleeding into the gastrointestinal tract should be absolutely diagnostic of carcinoma at the ampulla of Vater, but before we discuss what is wrong with that diagnosis, we might see the x-ray films of the chest.

DR CLAYTON H HALE The films taken at the first examination demonstrate a somewhat triangular shadow of increased density at the level of the anterior portions of the fourth, fifth and sixth ribs. In the lateral projection, this area of increased density is seen to lie posteriorly and there is a slight suggestion of rarefaction in the central portion of the mass. There is also evidence of a healed infarct in the left costophrenic sinus. The cardiac and vascular shadows and the remainder of the lung fields are not remarkable. No significant change is demonstrated on the films taken two days later. From the x-ray finding one must give first consideration to multiple infarcts but the possibility that the large area of density is due to metastatic cancer must be given serious thought.

DR MOORE How often do you see areas of diminished density in uninfected pulmonary infarcts?

DR HALE They are unusual. The possibility of this being a septic infarct must be considered if there is actual rarefaction in the area. The possibility of an abscess, although it is not at all typical,

CASE 32011

PRESENTATION OF CASE

A seventy-four-year-old man entered the hospital complaining of jaundice.

Ten years before admission the patient underwent a cholecystectomy. Gallstones were found. During the years after the operation he had several attacks of jaundice, each lasting a few days. Seven months before admission he began to have increasingly severe attacks of epigastric pain, radiating to the chest and to the right costovertebral angle. He also noticed nausea and frequent gaseous eructations. He had lost considerable weight. Ten days before admission jaundice and itching appeared and rapidly increased in severity.

On physical examination the patient was emaciated, weak and deeply jaundiced. The heart was slightly enlarged to the left. A systolic murmur and a diastolic murmur were heard at the apex. The right chest was more prominent than the left, which showed lateral flattening. Rales were heard at both bases. The abdomen was flat and soft. The

liver was tender and enlarged, extending four finger-breadths below the costal margin. An upper-right-rectus scar and a herniorrhaphy scar were present. The reflexes were normal.

The temperature was 98°F, the pulse 75, and the respirations 20. The blood pressure was 150 systolic, 85 diastolic.

The urine was normal except for a ++++ test for bile. The red-cell count was 3,820,000, with a hemoglobin of 12.8 gm. The white-cell count was 7200. The serum bilirubin was 28.5 mg per 100 cc, direct, and 30.3 mg indirect. The prothrombin time was 24 seconds (normal, 18 seconds). The bleeding time was 2½ minutes, and the clotting time 4 minutes. Clot retraction was normal. The total serum protein was 6.5 gm per 100 cc, with 4.3 gm of albumin and 2.2 gm of globulin. The nonprotein nitrogen was 19 mg per 100 cc, and the chloride 95 miliequiv per liter. A stool specimen was light brown and guaiac positive, it was slightly positive for bile.

An x-ray film of the chest taken on the first hospital day showed an area of hazy increased density

fibrous tissue. There were metastases to the regional lymph nodes and the wall of the common bile duct contained a 3-mm nodule of metastatic tumor, which had not eroded the mucosa. I wonder if this small nodule could have caused the pain.

The lungs showed a bilateral bronchopneumonia concentrated in the lower lobes. The density mentioned in the x-ray report was due, I imagine, to a 4-cm area of metastatic cancer in the left lower lobe.

DR MOORE: Perhaps his death was not so sudden as the record indicates. Was the cause of death bronchopneumonia?

DR SNIFFEN: I do not know why he died suddenly.

As incidental findings, the prostate was hyperplastic, with a large median bar, and one section contained a minute focus of primary carcinoma. The large median lobe had led to hypertrophy of the bladder, cystitis, a left hydroureter and ureteritis, and left acute and chronic pyelonephritis.

DR MOORE: You found no cause for the bleeding?

DR SNIFFEN: No, the duodenal mucosa was intact.

cannot be ruled out. A malignant neoplasm, either primary or metastatic, must also be kept in mind.

DR MOORE: How often do you see areas of diminished density in metastatic cancer?

DR HALE: We do not see them often.

DR MOORE: The x-ray films are confusing. From the written record I thought that the x-ray description was characteristic of pulmonary infarction, and the clinical course suggests two or three warning attacks, with a subsequent massive infarct and death. The area that Dr Hale says is suggestive of septic infarct and abscess is disturbing. It is difficult to believe that there was pulmonary supuration in a man who had a normal temperature and white-cell count. I shall have to reserve judgment on the pulmonary lesion and say that it was probably due to metastatic cancer.

What was the fundamental disease in the abdomen? I have said that many of the characteristic findings were those of carcinoma in the region of the ampulla of Vater, but there are some things wrong with that diagnosis. In the first place, the patient had quite a lot of pain. Carcinoma in the lower portion of the common duct and head of the pancreas is usually accompanied by painless jaundice. There is one explanation, however, for pain in this man. With obstruction to the common duct, the gall bladder is ordinarily greatly distended, and part of the clinical picture of carcinoma of the head of the pancreas is a big gall bladder, which serves partly to decompress the biliary tree. This man did not have a gall bladder to distend. Possibly this absence of a gall bladder accounts for the pain. It is also interesting that we have seen several patients in the last two years who had had previous gallstones and in whom the gall bladder had been removed, and who several years later developed carcinoma lower down in the biliary tree. It makes one wonder if cholelithiasis is part of the background of biliary-tract carcinoma in general, as well as of cholecystic carcinoma itself.

How about common-duct stone? I have already mentioned that it would be unusual for him to have had a long period free of pain if he had had a common-duct stone. It is rare for a person to walk around with common-duct stones for ten years, because they are intermittently extremely painful and should have caused trouble much sooner. If we knew that the gall bladder contained large gallstones and that the cystic duct was normal at the first operation, I should be willing to rule it out completely.

How about other tumors? A tumor higher in the biliary tree, away from the ampulla of Vater, can bleed down the duct and into the gastrointestinal tract, but that is very rare. Carcinoma of the duodenum is a possibility, but it, too, is extremely rare. What about carcinoma of the pancreas? He certainly could have had a carcinoma of the pancreas

that obstructed the duct, but because of the bleeding, I think that this was a lesion directly continuous with the lumen of the gastrointestinal tract. I have already discussed intrahepatic jaundice. Possibly his bleeding was from varices. How about carcinoma of some other organ? Dr Linton* has described several cases of carcinoma of the colon and duodenum in which continuity between the duodenum and the transverse colon had been established, with a duodenocolic fistula and jaundice. There was no barium enema on this man, such a diagnosis, however, is only a remote possibility.

As I have said before, I think that he had pulmonary infarcts, but it is too bad that we have no mention of what the lungs showed on physical examination. It might help us to decide on the pulmonary lesion.

My diagnosis, therefore, is carcinoma in the region of the ampulla of Vater. I rule out a common-duct stone. I believe that the cause of death was a massive pulmonary infarct and that the previous pulmonary lesion was an infarct. But the latter, as Dr Hale has pointed out, might have been a metastatic lesion or some form of abscess.

CLINICAL DIAGNOSIS

Carcinoma of pancreas

DR MOORE'S DIAGNOSES

Carcinoma at the ampulla of Vater, with direct invasion of the duodenum
Pulmonary infarction?
Pulmonary metastases?

ANATOMICAL DIAGNOSES

Papillary adenocarcinoma of head of pancreas, with metastases to common bile duct and lung
Early obstructive cirrhosis of liver
Jaundice
Bronchopneumonia

PATHOLOGICAL DISCUSSION

DR. SNIFFEN: At autopsy the patient was deeply jaundiced. The liver was dark green and enlarged, weighing 2050 gm. The sections microscopically suggested an early obstructive cirrhosis. The common bile duct was dilated down to the ampulla, which admitted a fine probe. The head of the pancreas seemed a little larger than normal, but the body and tail were atrophic and fibrous. Sections taken through the head of the organ showed microscopically a papillary adenocarcinoma, whereas the parenchyma of the body and tail had undergone atrophy, leaving the islets embedded in dense

*Linton R. R. Two stage operation for carcinoma of transverse colon producing duodenocolic fistula: report of two cases. *Arch Surg* 48: 197-207 1944.

giving increasing attention to a variety of programs designed to change existing arrangements between physicians and society. In times of rapid change it is even more than usually incumbent on physicians to know themselves, for theirs is the responsibility to direct the change in so far as it involves medical affairs. Physicians must continue to be educated, equipped, supported and stimulated to do a good job. To act intelligently they must know what kind of physicians America should have and in what kind of society these physicians are to work.

In these days when technical advance holds the center of the stage, most medical students have little opportunity to learn about either the relations between physicians and society or those between economics and disease. Few are able to approach the social or economic problems of the profession with the same intelligent attitude with which they face illness. Their education has been excellent from the technical point of view, but many of the fundamental problems besetting the profession of which they are about to become members have not been mentioned. Only a few students have interested themselves in these matters outside their studies.

Considerable impetus has been given to the teaching of such subjects by the Interim Report of the Social and Preventive Medicine Committee of the Royal College of Physicians of London.¹ Additional impetus has come from the establishment of a professorship of social medicine in Oxford University. An excellent definitive report has come from the latter source.²

As an experiment in teaching, in the winter of 1945 a series of nine lectures for third-year students was given under the auspices of the Department of Preventive Medicine of the Harvard Medical School, much of the stimulus having come from the

students themselves. The first of these lectures was devoted to the broad problem of the individual as a social being and to the effect of social and environmental factors on his health. The material in this lecture is considerably augmented by work on individual patients in the final medical-school year. The remaining eight lectures were given as a series on medical sociology. The lectures were concerned with the study of physicians and the

medical profession in relation to society. Forces determining the past, present and future structure of medical practice were considered. The obligations and responsibilities of the medical profession to society were brought clearly into focus. The speakers at all but the last three lectures were requested to present factual material and not their personal opinions or interpretations. It was thought

that after having heard the factual data, the student would be in a position to reach his own conclusions, and to agree or disagree with the various opinions and points of view expressed in the final lectures. That some of the lecturers committed themselves as advocates of change is both natural in a free society and healthy for the future of medicine. The majority of the students and physicians attending the lectures expressed the opinion that they were helped in objectively facing the problems before them.

In view of the general interest to the medical profession of the problems presented and of the apparent success of this experiment in teaching, these lectures will be printed in consecutive issues of the *Journal*, beginning with this week's issue. It is hoped that they will be provocative of thought and interest on the part of physicians.

PEPPER BILL

APPEARING elsewhere in this issue of the *Journal* is an informational report by the Subcommittee on Medical Economics of the Postwar Planning Committee that deserves careful reading by every member of the Massachusetts Medical Society

Last fall this subcommittee was faced with the responsibility of making recommendations concerning the Wagner-Murray-Dingell Bill (S 1050) and the Pepper Bill (S 1318). Since it was wisely decided that such action was impossible in the absence of clearly defined basic principles governing medical-care programs, the subcommittee proceeded to create a set of eight principles that appeared to be essential to any medical-care plan in a free society

Then, on the basis of these principles and of facts more generally regarded as necessary in medical care, the Pepper Bill was carefully studied

As indicated in its report, the subcommittee favors the objectives stated in the introduction to the bill but it also believes, for various reasons, that the bill does not represent the best form of legislation to accomplish what is intended

The report of the subcommittee has been accepted, with minor modification, by the Postwar Planning Committee, the Committee on Legislation and the Committee on Public Relations, and it will be presented to the Council of the Massachusetts Medical Society for acceptance as a joint recommendation

All this represents intelligent action. There is no doubt that the medical profession is threatened with national legislation that, if enacted, would largely abolish medical practice as it is known today. Nothing is accomplished by the mere statement that a plan is "no good." Constructive criticism is required in other words, those who are responsible for administering medical care and hence who are better informed concerning its practical aspects than are those not so engaged must point out *why* a scheme is unwise. In this way it is hoped that the desirable features of such plans can be promoted and that the undesirable ones can be avoided

MEDICAL SOCIOLOGY

"Know thyself" is a wise command. For physicians, knowledge of themselves implies a judgment whether or not they are doing a good job in an imperfect world. For the individual physician, this judgment is easy to make regarding his technical work, but is difficult to appraise in relation to his equally important social functions. In the latter sphere, the facts are hard to come by, the objectives are poorly defined, and the opinions encountered are often based on emotion

Physicians know that the world is changing at a breath-taking rate, and that the ways by which they serve the people need to be adjusted from time to time, if they are to continue to do a good job. Laymen are also aware of these facts and have been

ored by the Massachusetts Medical Society, as stated in the September 20 issue of the *New England Journal of Medicine*

Fee-for-service Under a fee-for-service system, practitioners, specialists and consultants are paid stated value for each unit of service rendered

In current plans the physician is required to submit to the administrative agency a clinical report and a bill or voucher for each service rendered. This entails the administrative costs of handling such reports and vouchers and may require the administrative agency to set up a system of cross index concerning the practices of each physician and the health of each patient

When a doctor cares for few patients under a medical-care plan, fee-for-service provides a remuneration that is proportional to the service rendered and thus covers the uneven incidence of illness among such patients

Under any system of payment, fee-for-service is an appropriate way to pay for consultant or for emergency services not rendered by the patient's family doctor

Under medical-care plans, experience shows that this method of payment is susceptible to abuse by a small percentage of physicians and patients. If the total budget of the medical-care plan is limited and demands are in excess of the funds, the payment per unit of service may be reduced

Per capita The per-capita system applies primarily to general practitioners. Under this system, practitioners are paid a certain sum per patient per year for each patient who elects him and whom he accepts. This payment is made regardless of the amount of care given to different patients or the fact that some patients will receive no service. A doctor being paid on this basis may be paid in addition for consultant or unusual services on a fee-for-service or per-case basis

The practitioner is required to notify the administrative agency when he first becomes the practitioner of a given person. This provides the administrative agency with the necessary information for remuneration of physicians. The administrative agency may from time to time request additional information from the doctor for study or other informative purposes. Physicians are usually given the choice of receiving remuneration quarterly, semiannually or annually

When a doctor cares for enough patients under a medical-care program to provide an actuarially sound distribution of risk due to the uneven incidence of illness among his patients, the per-capita method of payment permits economy in administrative burden with equity to the doctor

This method of payment is not susceptible to excessive care by the practitioner but is susceptible to excessive demands by the patient

Salary Under the salary method, a stipulated compensation for services rendered is regularly paid a physician, usually per week or per month

For certain physicians practicing as members of well organized groups or institutions, this form of payment provides a graded and predictable remuneration

It may provide the means of attracting a physician to a rural community to which he otherwise would not go because of irregularity of income

If groups of physicians or institutions contract to provide medical care either as consultants, specialists or practitioners, salary may in certain instances be a desirable form of paying for the medical care so provided

If provision is made on a merit basis for advancement and increased salary, the competition for high-salaried positions provides the incentive to a high quality of endeavor on the part of physicians, just as it does in other professions and occupations

This method of payment necessitates but little administrative paper work

Per case Under the per-case method a physician is paid a stipulated sum for the total service he renders a patient during a particular illness or because of a particular condition, usually within a stated time

It is particularly applicable to consultant or specialist services rendered to certain types of cases

Under the per-case basis a single clinical report and a bill are usually required to be submitted only at the termination of the services rendered

Per session The per-session method applies a flat rate of payment for the services rendered per stipulated session

Payment on this basis is particularly applicable to services rendered intermittently in group clinics

It usually requires the submission of a report of the physician's presence at the session

Cash indemnity Under the cash-indemnity system, payments are made by the administrative agency to the patient, not to the doctor. It provides for payment of a flat sum for wages for time lost because of illness or cash payments toward the cost of medical care according to a fee schedule, or both. Each person is free to make his own arrangements with those who furnish medical services as to both the amount of service and the charges for it

It provides no assurance that the money paid to the patient will be expended on medical care, and little control over quality or cost. Such supervision as would check on the expenditure of the funds for the medical care for which they were allotted and on the cost and quality of the care provided would entail an almost insurmountable task

Physicians might be obliged to spend time on examination for certification of illness to permit

MASSACHUSETTS MEDICAL SOCIETY

SUBCOMMITTEE ON MEDICAL ECONOMICS, POSTWAR PLANNING COMMITTEE

INFORMATION CONCERNING RECENT DELIBERATIONS

The Subcommittee on Medical Economics met on September 13, 1945, to study Senate Bill 1050, the so-called "Wagner-Murray-Dingell Amendment to the Social Security Act."

It was soon obvious that before any critical study of this or any proposed legislation could be made, certain guiding principles on which all could agree should be formulated.

It was also pointed out that Senate Bill 1318, the so-called Pepper "Maternal and Child Welfare Act of 1945," might soon come up in committee and that a study of this bill should take precedence over that of Senate Bill 1050.

It was, therefore, agreed that the committee should

- (1) Outline the important basic principles that were considered essential to a successful medical-care plan
- (2) Prepare a brief discussion of the various methods of payment for medical services
- (3) Study and prepare a critical report on Senate Bill 1318

Subsequent meetings were held on September 27, October 18, November 1, 2, 4 and 19 and December 10 for periods varying from five to seven and a half hours. Drs. Humphrey McCarthy, chairman of the Committee on Legislation, Joseph O'Connor, of Worcester, Stewart Clifford, of Boston, and Caroline Chandler of the State Department of Public Health took an active part in the discussions that followed and were most helpful to the subcommittee. What at times appeared to be widely divergent attitudes were, after free discussion, molded into this report.

The following basic principles were evolved as being essential to a medical-care plan in a free society:

- (1) The objective of adequate medical care in our free society is to make available to everyone—regardless of race, color, creed, financial status or place of residence—every known essential preventive, diagnostic and curative medical service of high quality. The attainment of such medical care must necessarily be an evolutionary process that will require the co-operation of all concerned over a period of years.
- (2) The success of any plan for medical care is dependent on the mutual co-operation of the public, those rendering professional services and the administrative agencies. This co-operation can be obtained only if those rendering the services are convinced that they will have a con-

tinuing authoritative voice in the formulation and execution of policies and plans, thereby assuming their proper share of responsibility.

(3) Provision of adequate medical care for those unable to obtain it by voluntary prepayment plans or by direct payment is the responsibility of the local or state government. Part of the burden of this responsibility may be assumed by charitable agencies. Federal grants-in-aid to state programs administered by state boards of health are an acceptable method of helping to meet this responsibility.

(4) The medical care of those who are able to purchase it by voluntary prepayment plans or by direct payment is the responsibility of the individual.

(5) Eligibility for receiving benefits under a program aided by federal grants should be determined by the individual states.

(6) The patient shall have free choice of his physician, group of physicians, clinic or hospital from among those participating in any plan, provided that the physician, group of physicians, clinic or hospital selected shall have the right to refuse to accept the patient.

(7) Physicians and other qualified persons rendering medical care should receive adequate remuneration for their services. Eventually this should include payment for services rendered to needy patients both in and out of hospitals.

(8) The physician shall be free to elect or reject without prejudice participation in a medical care plan. The rights of the physician as to the choice of methods by which he is to be paid shall be fully protected.

Methods of Paying Physicians Under Medical-Care Plans

In considering the various methods of paying physicians under such plans, several points must be kept clearly in mind to avoid drawing misleading conclusions from the experience of private practice.

First, in private practice, where the patient pays the bill, there is a deterrent to either excessive demands by the patient or excessive services by the doctor. In any plan where a third party pays the bill, this deterrent is largely removed regardless of the method of payment. Under medical-care plans, provisions against excessive demands should be made by specific clauses in the contracts or by establishing regulatory measures.

Second, under a medical-care program where patients are free to choose their physicians and doctors are free to accept or refuse individuals as patients, the stimulus to the patient and the doctor for establishing a satisfactory relationship is almost independent of the method of payment.

Third, the same opportunity for group practice pertains under any method of payment.

Incidentally, the subcommittee reaffirmed its approval of the Blue Shield prepayment plan spon-

HODGKIN'S DISEASE*

VI. Clinical Diagnosis

HENRY JACKSON, JR., M.D.,† AND FREDERIC PARKER, JR., M.D.‡

BOSTON

IN THE last analysis, the diagnosis of any type of Hodgkin's disease must rest on a properly executed biopsy. It is true that in certain advanced cases of Hodgkin's granuloma with generalized lymphadenopathy, evidence of involvement of internal organs, fever, polymorphonuclear leukocytosis and anemia, the diagnosis can be made with some degree of assurance on clinical grounds alone, but even under these circumstances experience has taught us that we may be mistaken.

We therefore advise the removal of a lymph node whenever feasible. The node must be selected with care and with due reference to any possible surgical risks. In all cases, a fair-sized node should be removed, for the small satellites toward the periphery of an involved area not infrequently show merely nonspecific inflammatory changes, and it is not easy to persuade a patient to submit to a second operation for no better reason than that the first one was unsatisfactory. Similarly, a lymph node already subjected to irradiation should be avoided unless there is an express intention to study the results of therapy, for the effect of irradiation is largely cytolytic, and the characteristic cells on which the diagnosis rests may therefore have been destroyed. It is further of the utmost practical importance that the tissue be immediately preserved in a suitable fixative and subsequently be properly cut and stained. The histologic features of Hodgkin's granuloma cannot be identified in poorly prepared tissue, nor, for that matter, can those of any of the malignant lymphomas.

GENERAL CONSIDERATIONS

For convenience, the differential diagnosis of Hodgkin's disease may be grouped under three headings: patients with simple localized lymphadenopathy,

those with generalized lymphadenopathy, with or without enlargement of the spleen, and those with constitutional symptoms of one sort or another, associated with little or no enlargement of the superficial nodes.

When confronted with simple lymphadenopathy apparently confined to a single region, one must consider various forms of lymphoma,—that is, giant-follicle lymphoma, reticulum-cell sarcoma, lymphosarcoma, Hodgkin's paraganuloma and Hodgkin's sarcoma,—as well as tuberculosis carcinoma, chronic inflammation, infectious mononucleosis, syphilis, leukemia and certain other conditions.

Without biopsy neither Hodgkin's paraganuloma nor Hodgkin's sarcoma can be distinguished from Hodgkin's granuloma. In the first of these, however, there are few if any systemic symptoms. The peripheral blood reveals no abnormalities, and the patient's general health is at first unaffected. The course is notably long. Most patients with Hodgkin's sarcoma are middle-aged or elderly, the disease being extremely rare under the age of thirty. The patient's health is usually disturbed, often seriously so, even early in the course of the disease. Pain and infiltrative, destructive lesions of the viscera are frequent. Fever and leukocytosis seldom occur except in its terminal stages. The course is rapid, and spontaneous remissions are extremely rare.

Giant-follicle lymphoma is indistinguishable clinically from Hodgkin's granuloma in its early stages except by biopsy.

Reticulum-cell sarcoma occurs in the older age groups, with the significant exception of primary reticulum-cell sarcoma of bone. The involved nodes are usually hard, and sometimes even stony hard, and have a tendency to become fixed to the surrounding tissues. Pain is frequent and often severe. Fever and leukocytosis are rare. Localized reticulum-cell sarcoma is likelier to be mistaken for carcinoma than for Hodgkin's granuloma. This is particularly true when the disease affects the tonsils or the gastrointestinal tract.

*From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard) and the Mallory Institute of Pathology, Boston City Hospital, the Department of Medicine, Harvard University, and the Pondville Hospital, Massachusetts Department of Public Health. This is the sixth of a series of seven papers covering the various aspects of Hodgkin's disease.

‡Associate professor of pathology, Harvard Medical School; pathologist-in-chief, Boston City Hospital.

the patient's collection of a cash indemnity rather than for the treatment of illness

Although the amount of administrative paper work concerning medical care would be small, that required by the professional certification of illness might be great

The Maternal and Child Welfare Act of 1945

The Maternal and Child Welfare Act of 1945 (Senate Bill 1318) has been carefully studied by this subcommittee. Although this subcommittee is in complete agreement with the objectives stated in the introduction to the bill, — "To provide for the general welfare by enabling the several states to make adequate provision for health and welfare of mothers and children and for services to crippled children," — it finds serious objections to the bill as written. Some of the more important of these are as follows

(1) The bill makes no adequate provision for general public-health programs that are more fundamental than this specialized legislation

(2) Services and facilities are available to all who elect to participate, regardless of economic status. This violates Basic Principles 4 and 5

(3) The public deserves a reasonable estimate concerning the ultimate cost of this proposed legislation. Experience and such factual data as are available indicate an ultimate annual budget of approximately one billion dollars. This should be clearly recognized in any consideration of the bill

(4) Fee-for-service method of payment is restricted to consultation or emergency visits and is not ordinarily available to practitioners or specialists

(5) The bill does not make clear just who is to decide the fee for a given service that would be considered adequate remuneration in an individual state, nor does it make provision for variable fees to meet the differing costs in the several states

(6) The bill does not prohibit professional personnel, groups or institutions rendering service under the program from accepting supplemental payment from or on behalf of patients

(7) The bill does not provide for payment to groups of physicians, clinics or hospitals providing professional services

(8) The bill does not emphasize the desirability of full utilization and further development of existing services and facilities

(9) The bill does not emphasize the necessity of restricting the development and expansion of a state program to the capacity of available administrative and professional resources

(10) The bill does not provide the professions rendering service a continuing and authorita-

tive voice in the formulation of policies and provisions of the bill may represent the attitude of the administrator rather than that of a given profession or group. This violates Basic Principle (11). The bill does not provide the facilities whereby the opinions of both the federal and state advisory committees are made available to the public

(12) Designation of the Children's Bureau as an administrative agency does not adequately assure proper integration of the health activities of the federal government

For these reasons we believe that the Maternal and Child Welfare Act of 1945 (Senate Bill 1318) does not represent the best form of legislation for the purposes for which it was written

LELAND S MCKITTRICK, *Chairman*

MISCELLANY

NEW SURGICAL HEAD AT BOSTON UNIVERSITY

Dr Reginald H Smithwick has recently been appointed professor of surgery and chairman of the Department of Surgery of Boston University School of Medicine and surgeon-in-chief of the Massachusetts Memorial Hospitals. Dr Smithwick was formerly associate visiting surgeon at the Massachusetts General Hospital and instructor in surgery at Harvard Medical School. Dr Smithwick, who is well known for his original contributions to the study and surgical treatment of hypertension and peripheral vascular diseases, will continue and extend his investigations. In this work he will have the close collaboration of the members of the faculty of the Boston University School of Medicine who have been engaged for several years in independent investigations of problems that are closely allied to Dr Smithwick's studies

NOTICES

ANNOUNCEMENTS

Dr Carlyle G Flake announces the reopening of his office at 300 Longwood Avenue, Boston, for the practice of diseases of the ear, nose and throat

Dr Henry A Kontoff, having returned from active service with the United States Navy, has resumed the practice of urology at 483 Beacon Street, Boston

Dr Walter S Levenson, having returned from active service with the United States Navy, has resumed the practice of general surgery at 370 Commonwealth Avenue, Boston

Dr Abraham Wolbarsht, having returned from active service with the United States Army, has resumed the practice of internal medicine at 375 Commonwealth Avenue, Boston

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tuberculosis Association, 554 Columbus Avenue, Boston, on Tuesday, January 15, at twelve noon. Dr Frank A Pemberton will speak on the subject "The Significance of Bleeding from the Female Genital Tract." Dr D D Hall will preside. Physicians are cordially invited to attend

(Notices continued on page 37)

Very rarely tuberculosis causes generalized lymphadenopathy. The differentiation of the two cannot be made clinically. The possible confusion of Hodgkin's granuloma with erythema nodosum has already been referred to.

In most cases with systemic symptoms, Hodgkin's granuloma is accompanied even in its early stages by enlargement of superficial lymph nodes, but this may not be so, and in this event the diagnosis can often be made only by exclusion.

Fever may be the presenting and indeed the only symptom for weeks or months, and this sign will later be discussed in detail. Its presence, particularly if it is relapsing in type and is not obviously due to one of the more usual causes, should arouse the suspicion of Hodgkin's disease. A careful search for enlarged lymph nodes especially in the abdomen, should be made, and x-ray studies may reveal the presence of involvement of the mediastinum. One of our patients had a relapsing type of fever for over a year prior to the development of any notable peripheral lymphadenopathy. True relapsing fever due to *Spirillum oberweileri* is practically never seen in this country. Undulant fever may now be diagnosed by appropriate laboratory tests. We have seen a case in which the presence of fever, cardiac murmurs, progressive anemia and a gradually enlarging spleen led to an incorrect initial diagnosis of bacterial endocarditis.

Rarely Hodgkin's granuloma begins with the symptoms of an acute upper respiratory infection — namely, chills, fever and cough. Such cases are almost always rapidly fatal. The tracheo-bronchial and mediastinal lymph nodes, the lungs and the pleura are frequently involved at the apparent onset. Usually, however, there is in addition the telltale superficial lymphadenopathy, either in the neck or in the axilla.

The differential diagnosis of mediastinal masses is always difficult. In our experience, a mediastinal tumor due to Hodgkin's disease is generally associated with enlarged cervical or axillary lymph nodes. The absence of such lymphadenopathy for any great length of time — two to six months — after the demonstration of the tumor is strong evidence that it is not due to Hodgkin's disease.

An adenomatous goiter, particularly if substernal, may cause diagnostic difficulties, for many of the symptoms and signs of hyperthyroidism, such as an increased metabolic rate, tachycardia, sweating, weakness, nervousness and even exophthalmos, may be present both in Hodgkin's disease and in other forms of lymphoma. If the question cannot be decided on clinical grounds, a determination of the organic iodine in the blood¹ will differentiate the two conditions, for in hyperthyroidism the iodine value is two to three times normal, whereas in Hodgkin's granuloma, even with an elevated metabolic rate, it is within normal limits.

Generalized itching, "eczema," weakness without other symptoms, abdominal pain, dyspnea, cough, hematemesis, melena, anorexia, amenorrhea, edema and a host of other nonspecific signs and symptoms testify to the protean character of the disease. In the presence of such symptoms, one can do no more than suspect that Hodgkin's disease is present and search for confirmatory evidence. Since well over 90 per cent of all cases eventually show enlargement of the superficial nodes, an opportunity to prove the diagnosis is usually at hand sooner or later.

PERIPHERAL BLOOD PICTURE

Hodgkin's Paragranuloma

No significant change is seen in the peripheral blood picture in patients with Hodgkin's paragranuloma.

Hodgkin's Granuloma

Much has been written concerning the changes in the peripheral blood picture of Hodgkin's granuloma. Without question marked deviations from normal are frequent, especially in the late stages of the disease, but when one considers its protean manifestations and the number of organs that are involved, it is not surprising that there is no uniformity of opinion about just what these changes are. Out of the confusing medley of hematologic studies, however, certain facts stand out as being of practical importance. There is no truly characteristic change that is, the disease cannot be diagnosed from a study of the peripheral blood alone.

A variable degree of hypochromic, or more rarely normocytic, normochromic anemia develops in a large proportion of cases, particularly in the late stages of the disease. In approximately one third of our cases — in all of which complete blood studies were done at each visit — the red-cell count eventually fell to 3,000,000 or lower. In 6 patients, 4 of whom were children, it was below 1,000,000. Children seem to be more liable to severe anemia than are adults. In 40 per cent of our patients under the age of twelve years, the red-cell count fell below 2,000,000, in contrast to 13 per cent of the entire group. The pathogenesis of this anemia is uncertain. In some cases it is apparently dependent on involvement of the bone marrow but that this is not invariably so is attested by the facts that in the patient in our series who had by far the most extensive bone lesions the count never fell below 3,600,000 and that in another patient who had a terminal count of 500,000 there was no evidence of bone involvement. In rare cases,^{2,3} there is hemolytic anemia of considerable severity, simulating in some respects, in so far as the peripheral blood is concerned, that of a congenital or acquired hemolytic anemia. In many of these cases there is a pseudomacrocytosis due to the presence of an increased number of reticulocytes. There may or

Lymphosarcoma, which is oftenest seen in childhood and in late adult life, is extremely rare between the ages of twenty and thirty years, a period of life during which Hodgkin's granuloma is frequent. The involved nodes that are the peripheral expression of lymphosarcoma are usually rather soft and tend to be of uniform size and distribution. Fever is rare except in the forms of the disease associated with acute lymphatic leukemia, in which it may be the most prominent symptom. The blood, however, frequently shows an increased percentage of lymphocytes, even in the absence of frank leukemia. Leukemia often accompanies lymphosarcoma or follows its development in children but is less frequent in adults.

Tuberculosis is extremely difficult to distinguish from Hodgkin's disease of any type, and it must be remembered that the two diseases occasionally occur in the same patient and, indeed, rarely in the same node. Redness of the overlying skin, fluctuation, caseation and sinus formation are not infrequent in tuberculosis, whereas they are extremely rare in Hodgkin's disease. It has been said that tuberculosis is prone to involve nodes in the anterior triangle of the neck, whereas Hodgkin's granuloma usually affects those of the posterior triangle, but this rule is treacherous. In our experience, large single nodes in the cervical or axillary region are likely to be tuberculous. The tuberculin reaction is usually positive in the presence of tuberculous lymph nodes, whereas it is almost always negative—even in high concentrations—in untreated Hodgkin's granuloma.

The presence of parenchymal disease of the lung should not be taken as proof that the entire process is tuberculous, for the pulmonary lesions of Hodgkin's granuloma may closely simulate those of tuberculosis, and the two diseases may coexist in the same person. Similarly, one should not be led astray by a past history of tuberculosis. Not infrequently proved tuberculous lymphadenopathy in childhood is followed by Hodgkin's granuloma in early adolescence or later life. The differentiation of these diseases can be easily made by biopsy.

Carcinomatous nodes are generally stony hard and are often fixed to the adjacent tissues, whereas the nodes in Hodgkin's granuloma, unless they have been heavily irradiated, are at most extremely firm. Carcinoma is likelier to cause pain, and the primary focus may be discovered and be patently cancerous. It must be remembered, however, that lymph nodes involved by rapidly growing carcinoma or sarcoma may be even softer than those of Hodgkin's granuloma, and that under these circumstances a clinical differential diagnosis may be impossible.

Chronically inflamed nodes secondary to a focus of infection that is often not obvious are not infrequently seen in children but are rare in adults. Small, pea-sized, painless, freely movable superficially situated nodes are, of course, often found

in the cervical and inguinal regions of many healthy adults. Their presence need cause no necessary alarm, but the persistence of a notably enlarged node or group of nodes especially if they are painless and fluctuate in size, calls for careful consideration whether a biopsy should be done. If there is any doubt, a node should be removed and the uncertainty thus removed. If there is only chronic inflammation, little has been lost, if the histologic picture is that of Hodgkin's granuloma, time has been gained. It must be constantly borne in mind that in many cases nodes affected by Hodgkin's granuloma fluctuate remarkably under the influence of coincidental nearby infection, and that the subsidence or even the virtual disappearance of cervical nodes should not be taken as proof that they merely represent chronic inflammation. This point is well illustrated by the following case.

R.S. (P13671), a 19-year-old girl, whose father had died of tuberculosis when she was a small child, in 1933 noted painless lymph nodes in the left side of the neck. For the next 5 years, these fluctuated greatly in size and varied in number, diminishing during the summer months and increasing during the winter particularly with the occurrence of upper respiratory infection.

In January, 1938, the patient developed a severe "cold" and the nodes increased greatly in size. There was some cough and considerable dyspnea, but there was no disturbance of the general health or loss of weight. A node was excised and showed the typical picture of Hodgkin's granuloma. X-ray studies revealed the presence of a small mediastinal tumor.

Whether the nodes observed in 1933 were actually the site of Hodgkin's disease must, of course, remain an open question. Earlier biopsy would have decided this point, and earlier treatment—had the nodes been granulomatous—might have aborted the disease.

Infectious mononucleosis occasionally simulates Hodgkin's disease. Usually, however, the diagnosis is clarified by the peripheral blood picture and is substantiated by the heterophil agglutination test. Rarely the lymphadenopathy and splenomegaly of infectious mononucleosis remain for months after the subsidence of the acute disease. Under these circumstances, a careful history is important, and biopsy may be necessary.

Syphilis should cause no confusion if due attention is paid to the history and to the appropriate laboratory tests. We have seen a case, however, in which following a frozen-section diagnosis of lymphosarcoma a breast amputation and axillary dissection were done, the patient proving to have secondary syphilis. Parenthetically, it may be said that in malignant lymphoma a frozen section is an extremely slender reed on which to lean.

Lymphatic leukemia, rare in the twenties and thirties, is accompanied by the characteristic peripheral blood picture.

Rarely myelogenous leukemia is accompanied by generalized lymphadenopathy or enlarged nodes in a single region. The characteristic blood picture should make the differential diagnosis clear.

area Too often such lymphadenopathy is regarded as due to the infection alone, it is too infrequently recognized that lymph nodes involved by Hodgkin's granuloma but not greatly enlarged may rapidly increase in size after what appears to be a simple infection

There is a peculiar and characteristic reaction that deserves special attention—so-called "Pel-Ebstein fever" In 1887, Pel⁶ and Ebstein⁷ independently described a relapsing form of fever characterized by periods of pyrexia, alternating with intervals during which the temperature is normal or subnormal The febrile periods are marked by a gradual daily increase in temperature to 104°F or more and a subsequent equally orderly decline to normal The pulse and respirations usually follow the temperature in such a manner that when the latter is 104°F the pulse is 120 to 150 and the respirations are 30 to 35 During the period of increased temperature, most patients feel extremely ill There follows an afebrile period of weeks or months, during which the patient may return to apparently perfect health, but sooner or later the fever returns and the afebrile intervals become shorter, and eventually the fever becomes continuous

This syndrome, although usually referred to as Pel-Ebstein fever, was accurately described by Murchison⁸ in 1870 in a case of so-called "lymphadenoma"—the British term for Hodgkin's granuloma By rights, if any man's name is to be attached to the syndrome it should be Murchison's

Mac Nalty⁹ has made a special study of the fever in Hodgkin's disease

The following case is illustrative of Pel-Ebstein (Murchison) fever

F C (P2903), a 22-year-old house painter, entered the hospital on January 20, 1931 In the spring of 1930, he noted a painless lump the size of a walnut in the left side of the neck This was removed at another hospital and showed the usual histologic picture of Hodgkin's granuloma At that time there were no other symptoms, and the patient was lost sight of In October, 1930, he began to have attacks of fever, malaise and anorexia These lasted for 10 days or so and recurred after an interval of apparent good health, about every 6 weeks During each attack the patient was confined to bed and extremely prostrated, but between attacks he felt perfectly well Each febrile episode was ushered in by a marked sense of drowsiness and anorexia, and the temperature rose higher each night until by the end of 5 or 6 days it had reached 104 or 105°F It then gradually subsided to normal by about the 15th day During the febrile period there was marked anorexia, sweating and extreme prostra-

tion As soon as the temperature became normal the patient again felt quite well and was able to resume his daily work

Physical examination on entry showed no abnormalities except for a small scar in the left side of the neck An x-ray film of the chest showed a slight increase in the mediastinal shadow There was slight anemia The white-cell count was normal but the differential count showed 90 per cent polymorphonuclear leukocytes and 10 per cent lymphocytes

Following x-ray therapy to the chest the small mediastinal mass disappeared, but there was no symptomatic improvement, and the patient continued to have recurrent attacks of fever, malaise, extreme weakness, anorexia and fleeting generalized pains The intervals between attacks constantly became shorter, and the fever finally became continuous X-ray therapy had no effect, and Fowler's solution in large doses caused no improvement

Four months after entry, the liver and spleen became palpable One month later, jaundice appeared and the spleen reached the umbilicus, but there was still no peripheral lymphadenopathy Anorexia was extreme and loss of weight very marked, and drowsiness became a more and more prominent feature The patient's strength rapidly failed, and he died on April 17, 1931, about 7 months after the onset of the generalized symptoms and 1 year after the first symptom of painless lymphadenopathy

Autopsy Post-mortem examination showed widespread Hodgkin's granuloma, with scarcely an organ spared The main lesions were chiefly in the liver, the spleen and the retroperitoneal and mediastinal lymph nodes

Uddströmer⁵ found this type of fever in 7 per cent of his cases, in our series it was present in 5 per cent

Hodgkin's Sarcoma

Fever occurs in approximately one third of the cases of Hodgkin's sarcoma, although it follows no particular pattern and is rarely very high, not infrequently, however, one sees a septic type of temperature reaching a daily peak of 102°F Pel-Ebstein (Murchison) fever does not occur Definite chills are occasionally seen, and in patients having them the prognosis is extremely bad We have never had such a patient who lived more than two years after the apparent onset of the disease

may not be alteration in the fragility of the red cells. The exact explanation of this hemolytic anemia in Hodgkin's granuloma is yet to be determined.

It is generally agreed that although the white-cell count is rarely normal throughout the disease, leukocytosis is extremely frequent, and that, on the other hand, extreme leukopenia may occur. Sixty-three per cent of our patients had a white-cell count of 11,000 or over. In 12, the count was at one time or another above 25,000. The leukocytosis occurs quite independently of fever. Marked leukopenia occurred in 12 per cent of the cases. There seemed to be no correlation between the clinical findings and the leukopenia, but in certain cases the latter seemed to be due to irradiation, especially when this had been applied to the abdomen. Marked fluctuations in the white-cell count may occur within a short period of time and without apparent cause.

Certain significant changes take place in the differential white-cell count. By far the most constant one is a relative or absolute increase in the percentage of polymorphonuclear neutrophils, a point on which all investigators are agreed. In 81 per cent of our cases, this percentage was at one time or another over 75, in 5 cases, it was 95 or more. This change tends to become increasingly more pronounced as the disease advances. There is a strong tendency toward a shift to the left, and myelocytes in varying proportions are not rare. They were found, usually in small numbers and inconstantly, in 11 per cent of our cases.

An occasional case shows an increased number of eosinophils. Baldrige and Awe⁴ report a case with a white-cell count of 43,000 and 83 per cent eosinophils. Uddström⁵ found over 6 per cent eosinophils in only 12 per cent of his cases, and was unimpressed either by the importance of eosinophilia in the disease or its relation to itching, which has been stressed by many writers. In our experience, marked eosinophilia is rare, and when one recalls the large variety of conditions accompanied by an increase of these cells, it seems not improbable that in certain cases, at least, the eosinophilia is unrelated to the Hodgkin's granuloma.

Monocytes are frequently increased in number, and in rare cases greatly so.

The number of platelets shows no constant change, although they are not infrequently moderately increased.

In summary, the most frequent blood changes in Hodgkin's granuloma are a normochromic or hypochromic anemia, a moderate increase in the white-cell count and a moderate to great increase in the percentage of polymorphonuclear neutrophils.

Hodgkin's Sarcoma

A moderate degree of anemia—usually hypochromic, occasionally normocytic and rarely macro-

cytic—is seen in Hodgkin's sarcoma. In only a small percentage of the cases, however, does the anemia become extremely marked. In 5 of our cases, the red-cell count was below 2,000,000, with a correspondingly low hemoglobin. One of these patients may possibly have had a hemolytic type of anemia, for the icteric index was 50 and there was nothing to account for the jaundice. Fragility tests were not done, however, so that one cannot be categorical on this point.

The white-cell count is usually normal, rarely it is moderately elevated. The percentage of polymorphonuclear neutrophils is almost invariably high, and in approximately one third of the cases there is a marked increase in the percentage of monocytes. Myelocytes occasionally occur.

There seems to be no correlation between the hematologic findings and either the organs involved or the course of the disease.

FEVER

Hodgkin's Paragranuloma

In patients with Hodgkin's paragranuloma, fever does not occur.

Hodgkin's Granuloma

Fever of one type or another, unaccompanied by sepsis or incidental and unrelated infectious diseases, is an extremely frequent finding in Hodgkin's granuloma. Uddström⁵ in Sweden reported that fever was present in 54 per cent of 484 collected cases. In our series, it occurred at one time or another in at least 43 per cent, it is probable that the incidence would have been higher if every patient had been constantly observed throughout the course of the disease.

The fever may be of various sorts. Most frequently it is, as Uddström puts it, "typeless." Occasionally it is intermittent or remittent, reaching 101 to 105°F every day. More rarely a high continuous fever is seen. Such a finding is almost always terminal. It is common knowledge that pyrexia becomes increasingly frequent as the disease advances.

During febrile periods unassociated with sepsis it is usual for the lymph nodes to increase in size, splenomegaly, if it exists, frequently becomes more marked, and the patient is generally prostrated, weak and debilitated. Tachycardia, sometimes extreme, almost invariably accompanies the fever. Occasionally, however, one sees a patient who, in spite of a moderate increase in temperature—99 to 101°F—feels perfectly well and is, indeed, unaware of any febrile reaction, and the fact that peripheral lymphadenopathy is absent or inconspicuous at the time may render the correct diagnosis extremely difficult.

Infections, particularly those affecting the upper respiratory tract, are prone to cause coincident enlargement of lymph nodes close to the affected

classified as a psychoneurosis. To say that these patients are not psychiatric cases because there is no name for them except "gold brickers," "inadequate personalities" or "opportunists" is to neglect a serious problem, for the number of hospital beds occupied by this type of patient is large, and will be proportionately larger in veterans' hospitals after the war.

The definition under discussion need not exclude patients who suffer from some organic disorder but whose incapacitating symptoms are primarily nervous or emotional. It is evident that many situational and symptomatic disorders of this kind masquerade under such terms as "gastritis," "colitis," "effort syndrome," "myositis," "rheumatism," "eye strain," "neuritis" and "neuralgia" — to mention only a few. The inefficiency and failure of many of these persons are frequently more closely related to emotional instability or lack of tolerance of the military situation than to defective functioning of the organ in question. This broad definition of nervous breakdown may be objected to as being all-inclusive, and it is admitted that there are many men on the wards in military hospitals who would probably never consult a physician in peacetime, unless it were to obtain an excuse for inability to carry out life's obligations in a satisfactory manner. Such patients' disability or failure in performance is largely one of loss or lack of morale. They constitute casualties fully as much as do men with wounds, and in addition they have a much more damaging influence on the morale of the group to which they belong.

The retreat of the British from Mons in World War I is cited as an instance of stress so severe that many broke under the strain.¹ One should, however, not lose sight of the fact that appreciable numbers did not break down — notably those who stood, fought and won in the Second Battle of the Marne. In this war it would be of considerable interest and value to know the actual percentage of nervous breakdowns among those who were evacuated at Dunkirk, among the men who fought on Guadalcanal or among the troops engaged at Stalingrad, Anzio, Dieppe, Tarawa and Iwo Jima. If one happens to see a large number of neuropsychiatric patients from the same combat zone, one is apt to conclude that these casualties were unusually high, whereas actually one may know little of the total number of troops involved.

One cannot base a diagnosis of mental disorder entirely on the symptoms presented. The patient's attitude toward them is far more important than their degree of severity. One sees many men returning from combat or operational duty and many survivors of ship sinkings who are anxious to carry on in the face of distressing somatic symptoms. This has been observed both in officers and among the enlisted personnel. The essential feature seems to be a high morale or sense of duty, dependent

primarily on the stability of the personality prior to entry into the service. The presence or absence of morale in an individual or a group is a complicated matter. Morale depends on many factors, two of which appear to be of outstanding importance. One is the inherent emotional stability of the person, the other is his quality of leadership or confidence in leadership. There are many men with a defective emotional adjustment who are held in line by the *esprit de corps* of the group, being profoundly influenced by leadership, who break down when this protective influence is removed or regain their morale if effective leadership is provided. It must be borne in mind, however, that a large percentage of men in a given unit do not break down mentally, irrespective of what may happen to their leaders. It is true that the military effectiveness of any unit may be gravely influenced by a relatively small percentage of casualties of whatever type, and particularly by mental casualties. If competent, skilled and resourceful leaders take over such a demoralized unit, their task is not so hopeless as might appear at first glance, since they are dealing with a group that has had its most unstable men screened out by exposure to combat, so that those who remain, together with replacements, have not had nervous breakdowns. This is not meant to detract in any way from the role of leadership in producing an effective fighting unit or to oversimplify the problem of the maintenance of morale. It is intended only to point out that at times too much attention is focused on the man who breaks down mentally. An entire unit may be branded as "NP" or "psycho" even though the unit has a relatively low mental-casualty rate, the men who have stood up under all kinds of trying circumstances being lost sight of. The emotionally unstable are evacuated to safer zones and are eventually returned home, the majority being discharged from the service with varying degrees of disability. For the larger percentage of men who did not break down, "Valor-like virtue is its own reward" and may turn out to be a reward full of bitterness in the postwar period, if society fails to provide adequate opportunity for the veterans who are chiefly responsible for the winning of the war.

It has been the practice at this center, when examining sailors from various fighting ships or marines who had been through a strenuous campaign, to ask whether they knew of anyone aboard their ship or in their outfit who broke down mentally. The questions were asked both of men who showed evidence of emotional disorder and of those who did not. The replies appear to be of some significance. Without exception these men knew of only one or two others who had suffered a breakdown, and in some instances an entire ship's crew or company of marines had no psychiatric casualties.

It is realized that this method of acquiring data will not bear critical evaluation, since a fair number

MENTAL BREAKING POINTS*

COMMANDER JOHN B. DYNES (MC), USNR †

IF THE psychiatrist interviews servicemen who have broken down mentally day after day, month in and month out, he is likely to conclude that all men have mental breaking points, furthermore, he may wonder how it is possible that the United States is winning the war. His outlook on life and his interpretation of human behavior are apt to be colored, if not strongly influenced, by the symptoms and diseases that he finds in his patients. It is evident that all patients referred to the psychiatrist in a military hospital must have mental symptoms of some type. To decide that all men have mental breaking points on the ground that all those whom the psychiatrist interviews have shown one, or have had nervous breakdowns, appears to be drawing general conclusions from an extremely small and badly chosen sample.

In the past year the popular press has issued many warnings and even appeals to the public, and in particular to the families and friends of servicemen, on what to do or say, or what not to do or say, when veterans come home. Most of this advice is sincere but misdirected. If applied to those who have developed nervous or mental disorders it might be of more value, although one should avoid generalizations and should treat each man according to his needs. The reaction against this type of advice among men in the service who are in good physical and mental health is in many cases one of resentment and annoyance. It is believed that the basic reason why the majority of returning veterans are disturbed by the special treatment accorded them by their family and friends is that they are getting the treatment intended, not for them, but for the psychiatric war casualties, among whom they do not belong.

Why should this error occur? The explanation is thought to lie in the belief or theory, held by laymen and by physicians alike, that all men have mental breaking points or can take only so much, or, to put it another way, that all men are apt to "crack up" or have a nervous breakdown if the stress of combat or military life is severe enough.

One not infrequently hears such a remark as "It was more than he could bear," "A man can only take so much," or "He couldn't take it any longer." These statements are widely used by laymen to denote a nervous breakdown in the face of overwhelming misfortune or severe environmental stress. The emphasis is frequently placed on "an unkind fate" or on "outrageous fortune," over which the individual has no control. The victim

is supposedly caught in the toils of circumstance and irresistibly crushed. Since World War I considerably more attention has been paid to the individual than to the environmental stress, and there appears to be an unofficial but fairly general agreement among psychiatrists in the armed forces that the stability of a man's personality prior to entry into the service is more important in the maintenance of mental equilibrium than is the severity of the combat stresses to which he may have been subjected.

Obviously, the terms "breakdown" and "breaking point" have physical and mechanistic origins and are used only metaphorically — but nevertheless effectively — in referring to mental disorders. Such terms as "stress," "tension," "pressure," "weight," "force" and "impact" have been borrowed because they are descriptive, and because analogies can be easily drawn, supported or reinforced by their use. Psychiatrists use the term "nervous breakdown" with caution, preferring some such descriptive or diagnostic term as "psychoneurosis," "dementia praecox" or "psychopathic state" — to mention only a few of these — denoting the character or trend of the disorder. These terms are labels, at times hardly more satisfactory — and certainly more confusing to the layman — than "nervous breakdown." It is evident that any expression of this kind must be related to some frame of reference that indicates inefficiency or failure in performance, such as unfitness for military duty, for life in the community — involving mental institutionalization — or for work. In each case the essential element is a failure of performance or loss of efficiency for the task assigned, which may vary both qualitatively and quantitatively. For practical purposes in this paper, the term "nervous breakdown" refers to such failure of efficiency that is directly or indirectly related to an emotional or mental instability that necessitates medical care. So long as such a man remains a patient in a medical unit, he is an ineffective person so far as the military service is concerned.

Such a definition of nervous breakdown obviously includes a wide range of mental disorders, from low morale, with its aversion to fighting and hardships, to major psychoses. It is also applicable to those self-centered persons who are feigning or exaggerating various somatic complaints to escape military duty. It is evident to many neuropsychiatrists working in military hospitals that a great many patients on medical, surgical and psychiatric wards suffer from a certain lack of morale or failure in performance that is not dependent on unconscious mental conflicts and should certainly not be

retained have repeatedly proved themselves to have stable personalities

* * *

It is obvious that not all men suffer mental breakdowns under severe stress. It is not meant to imply that the human organism is indestructible, since physical exhaustion and organic disease are bound to take their toll, or that a person under prolonged and severe stress may not fail in some manner other than mental. To argue whether a stable personality develops a nervous breakdown if just the proper set of stresses happen to strike at the same time is profitless. But this is not a question of practical importance, since experience shows that the great majority of fighting men are capable of absorbing the shock of all the blows to which they are subjected without showing signs of a nervous breakdown.

It would be erroneous to judge the mental health of all men under arms by the picture presented on the neuropsychiatric wards of military hospitals. It would be just as erroneous to assume that the 10 men out of 2000 cited above represented all

those who may subsequently break down mentally under service conditions. It is apparent that men with stable personalities are much less susceptible to the stress of military service in wartime than are those having poorly balanced or defective personalities. It is principally the man with a defective or maladjusted emotional life who is likely to break mentally under the stress of military duty, and although it is generally believed that even the most stable personality may crack under the strain of combat, this state of affairs is exceedingly rare. All that can be said with certainty is that only those who actually break have mental breaking points, and that experience, at a naval receiving station in examining men fresh from combat and noncombat duty and survivors of ship sinkings does not support the widely accepted theory that all men have mental breaking points.

THE INCIDENCE OF LEUKEMIA IN RADIOLOGISTS*

HELMUTH ULRICH, M D †

BOSTON

EXPOSURE to x-rays has for some time been regarded as a possible cause of leukemia. This belief is based in part on results obtained by experimental exposure of animals to x-rays¹⁻⁴ and in part on several reports of cases of leukemia occurring in workers exposed to radiation.⁵⁻¹⁵ Definite proof of such an etiologic relation has not been established, however, and some authors have expressed doubt concerning it. Thus, Evans and Roberts⁸ stated in 1928, after a review of the literature to that date, "Although the possibility of causal association cannot positively be denied, the evidence is not conclusive." Haagensen⁹ wrote, "Doubt may be raised as to the relationship of the exposure to radiation and the development of leukemia," and Warren and Dunlap,¹⁶ in their comprehensive review published in 1942, stated "Few examples of leukemia have been described in persons chronically exposed to radiation. Only 24 case reports are found in the literature if one excludes all reports of leukemia following the therapeutic irradiation of lymphatic tumors."

More recently, Henshaw and Hawkins,¹⁷ having found that none of the existing evidence furnishes any direct proof that radiation actually acts as a carcinogenic agent in the induction of leukemia in

human beings, determined the incidence of leukemia in physicians from the death notices published weekly in the *Journal of the American Medical Association* and compared it with similar data regarding the general population, derived from the vital statistics of the United States Bureau of the Census. They found that during a ten-year period (1933-1942) 0.53 per cent of physicians died of leukemia, as compared with 0.39 per cent of the general population. After making corrections for differences of age, sex and other factors that influence the outcome, they arrived at the following conclusion: "Leukemia was recognized approximately 1.7 times more frequently among physicians than among white males in the general population." They stated that, although these observations furnished no direct proof that radiation acts to incite leukemia in human beings, they were nevertheless in accord with the findings on experimental animals in which exposure to x-rays had been found to increase the incidence of leukemia.

Since the majority of physicians are not subject to exposure to radiation, it seems that a comparison of the incidence of leukemia among radiologists and that among other physicians should give more conclusive results. The present report is based on a statistical study of deaths of physicians reported in the *Journal of the American Medical Association* during the ten-year period 1935-1944.

of men have a delayed reaction and may not develop their mental disorder until later, and since the casual observer is apt to mistake the true diagnosis in certain cases or to misinterpret unusual behavior. It is, however, not necessary to rely on such hearsay, particularly when more reliable information is available. The psychiatrist at a naval receiving station has an unusual opportunity of interviewing all the survivors of sunken ships and all men returning from combat or naval operations. The type of screening thus accomplished is unlike any other, but most closely resembles that done at induction centers, with an important difference: all men interviewed had been subjected to the test of combat or overseas duty. It can hardly be said that they had not been subjected to the type of stress that precipitates a nervous breakdown in susceptible persons.

The significant fact concerning these men returning from overseas is that so few of them showed any evidence of emotional instability or nervous breakdown. The great majority declared that they had never experienced any disabling nervous symptoms, even though many had been in combat on a number of occasions. It was true that the majority admitted that they had experienced fear and its attendant autonomic symptoms, but exceptionally few had been incapacitated by fear.

Two thousand men were given a questionnaire, the Cornell Selectee Index,² a short psychiatric or psychosomatic inventory consisting of sixty-four questions designed to elicit evidence of emotional instability. In addition, each man was interviewed. Of these 2000 men, 500 were survivors of sunken ships, 1000 had returned from combat duty, and 500 were being returned from overseas duty. Many of the latter from advanced outposts, where the stress of military duty is said to be even more trying than that of actual combat. Only 10 showed evidence of nervous breakdown according to the definition given earlier in this paper. These men showed evidence of emotional instability, with an increased startle reaction, increased fatigability, tremors, palpitation, insomnia, nightmares, headache, irritability, gastrointestinal disturbances, anxiety and depressive reactions, severe enough to render the victim unfit for military duty and to warrant sending them to a naval hospital.

Table 1 shows the percentage of each group of men giving twenty-five or more positive answers. It is claimed that this method of scoring screens those having a severe degree of emotional maladjustment. It is of interest that although 5 per cent of the 2000 men showed evidence of severe nervous symptoms, all but 10 of these had been able to serve in the armed forces overseas without developing evidence of a nervous breakdown. It would be erroneous to assume that these 90 men had been missed in answering this index. Personal interviews ruled out this factor and established a previ-

ously mentioned principle, namely, that symptoms alone are not indicative of a nervous breakdown, the subject's attitude and reaction toward them being far more important than their severity.

This low percentage of men with a significant nervous disorder was at first somewhat startling, since the psychiatrist had rarely had an oppor-

TABLE 1 *Cornell Selectee Index Scores of Returned Personnel*

GROUP	NO OF MEN	PERCENTAGE WITH SCORES OF 25 OR MORE
Men returned from combat duty	1000	6
Men returned from noncombat duty	500	6

Total	2000	
Hospitalized for nervous breakdown	10	100

tunity to interview men who had been through combat or the prolonged stress of trying overseas conditions and had continued to maintain their mental equilibrium. It may be argued that a certain number of men had been hospitalized for nervous disorders prior to the return of their units to this country, and also that some of those interviewed may be expected to develop disabling nervous symptoms many weeks or months after their experience, but even allowing for these cases, the percentage of men who develop a nervous breakdown under the stress of military service is extremely small if compared to the total number in the service. This group of psychiatric war casualties should be adequately cared for, and those familiar with the military services know that such rehabilitation programs are under way at the present time.

It is believed that there has been considerable overemphasis on the serious consequences to the man who has been in combat or under the prolonged stress of military operations. It is not the intention of this paper to minimize the important work done by psychiatrists in the detection, elimination and care of psychiatric war casualties. It is thought, however, that a complete over-all picture of the mental health of the men in the armed forces is not reflected by the reports in the popular press nor by those emanating from military hospitals, for it is evident to psychiatrists serving in such military activities that they see only those who have broken down mentally or have failed in the performance of their duty, and thus tend to lose their perspective regarding the mental health of all men under arms. It should be apparent that even though the definition of nervous breakdown given above is broad, the percentage of men in the service who have had such a disorder is relatively small.* This is due in part to the excellent work done by psychiatrists at induction centers and training stations—frequently working under considerable handicap—in the elimination of the psychiatrically unfit. The great majority of those

ICE CREAM AS A SOURCE OF RIBOFLAVIN, CAROTENE AND ASCORBIC ACID*

ARTHUR D HOLMES, PH D,[†] JOHN W KUZMESKI, B S,[‡] CARLETON P JONES, M S,[§]
AND FRANK T CANAVAN[¶]

AMHERST, MASSACHUSETTS

MANY people consider ice cream as a luxury food, a dessert or an attractive adjunct to teas and other social occasions where light refreshments are served. Consequently this food does not ordinarily receive proper recognition as a valuable source of protein, fat carbohydrate, minerals and vitamins all of which are essential dietary constituents. In fact most people fail to realize the extent to which ice cream is consumed in this country. It is reported that 412,144,000 gallons were used during 1943,¹ or over 3 gallons for every man, woman and child. It is difficult to estimate accurately the retail value of this ice cream, since large quantities are retailed in cones of various sizes and as individual servings at stores and resorts, but on the basis that ice cream retails for 75 cents a quart, the retail value of ice cream consumed in 1943 amounted to at least \$1,236,432,000. This is about one fourth the retail value of the whole milk and over twice the retail market value of the eggs, apples or potatoes consumed annually.² A survey of the literature, however, failed to reveal much information concerning the vitamin content of this valuable food, and this study was conducted to accumulate data in this connection.

PREPARATION OF ICE CREAM

The coffee, maple and vanilla ice creams used in this study were made at the Dairy Manufactures Laboratory, under the conditions maintained for training students and for the preparation of ice cream for the Massachusetts State College dining halls. The ingredients for 100 pounds of ice-cream mix were 24 1/4 pounds of cream (40 per cent), 56 3/4 pounds of whole milk, 15 0 pounds of cane sugar, 4 0 pounds of skimmed milk powder, and 0 3 pounds of gelatin. The whole milk and cream were produced by the college herd of Ayrshire, Guernsey, Holstein, Jersey and Shorthorn cows fed and maintained under conditions similar to those of local progressive commercial dairies.

The ingredients were thoroughly mixed and pasteurized by the holding method at 145°F for thirty minutes. When pasteurization was completed, the mix was passed through a homogenizer at 145°F under 2500 pounds pressure per square inch to break up the fat globules and obtain a product of uniform composition. The ice-cream mix was cooled to 40°F and allowed to blend or ripen

for eighteen hours. At this stage of manufacture, the ice cream weighed 9 25 pounds per gallon. The mix was then placed in a batch freezer, and flavoring was added at the rate of 6 ounces of vanilla, 32 ounces of coffee extract or 12 ounces of imitation maple flavor per 100 pounds. During the freezing process the flavoring was intimately incorporated and sufficient air was whipped into the mix so that the final ice cream weighed 5 pounds a gallon. Thus, essentially half the volume of the finished ice cream consisted of occluded air. The finished ice cream was placed in commercial 4-ounce cardboard containers and held in a refrigerator at -10°F. This ice cream was not strictly comparable to the present-day wartime commercial product, since the latter ordinarily contains only about 10 per cent of fat, whereas the ice cream used in this study contained 12 per cent of fat.

ASSAY PROCEDURES

Carotene

The carotene content of the ice cream was determined by a modification of the method of Boyer, Spitzer, Jensen and Phillips.³ Briefly, the procedure was as follows. A 20-gm sample of ice cream was extracted with 30 cc of alcoholic potassium hydroxide solution—40 gm of potassium hydroxide completely dissolved in 50 cc of distilled water and thoroughly shaken with 180 cc of ethyl alcohol—and allowed to stand for three hours. Twenty-five cubic centimeters of diethyl ether was added and the mixture was vigorously shaken for one minute. After the second extraction with ether, the two extracts were combined, 25 cc of Skellysolve B was added, and the mixture was vigorously shaken for fifteen seconds. Twenty-five cubic centimeters of 80 per cent methyl alcohol was added and the mixture was shaken for one minute. The alcohol-water-ethyl ether layer was discarded. Fifty cubic centimeters of 3 per cent sodium sulfate solution was added and the mixture was vigorously shaken four separate times. The water layer was discarded. Ten cubic centimeters of Skellysolve B was added and the Skellysolve layer was filtered through No 41 Whatman filter paper containing about 5 gm of anhydrous sodium sulfate into a 50-cc amber flask. The separatory funnel was rinsed with Skellysolve, and the filter paper and sodium sulfate were washed with separatory rinsings until a volume of 50 cc had been reached. The regular procedure was then followed.

Riboflavin

The following procedure was used to determine the riboflavin content of ice cream. Ten grams of ice

It must be admitted that the results cannot be perfect, first, because, as indicated by Henshaw and Hawkins,¹⁷ the cause of death is not given in about 25 per cent of the obituary notices, and second, because in an even greater number there is no indication of possible x-ray exposure. For example, some of the physicians not listed as radiologists but dying from leukemia may have been exposed to radiation, — the case reported at the end of this article is of this type, — which would increase the incidence of leukemia in the exposed group. Conversely, some unexposed physicians, the cause of whose death is not given, may have died of leukemia, which would increase the incidence in this group. It is not unreasonable, therefore, to assume a tendency of the various unknown opposing factors to balance each other. At any rate, if the difference between the two groups is sufficiently large, it should not be significantly affected by these discrepancies.

From 1935 to 1944, inclusive, the deaths of 34,626 physicians were recorded in the *Journal of the American Medical Association*. Two hundred and five of these men were listed as radiologists. The total stated number of deaths from leukemia is 158. Eight of these occurred among the 205 radiologists, giving a percentage of 3.9, 150 were among the 34,421 physicians not listed as radiologists, a percentage of 0.44. Therefore, those known to have been exposed to radiation had an incidence of leukemia more than eight times as great as those who are not listed as radiologists. Although this difference may be affected somewhat in either direction by the previously discussed lack of complete information, it seems too great to be wiped out or to be significantly modified.

This statistical study, which supplies substantial evidence that exposure to radiation is a potential cause of leukemia, was suggested by the occurrence of this disease in a physician who had repeatedly been exposed to radiation over a long period of time. The following data summarize the findings in this case.

R. J., a 51-year-old dermatologist, had for several years failed to take precautions against exposure to radiation that he used for treating his patients. Symptomatically his illness began in the fall of 1941, the major complaint consisting of pain in various parts of the body, especially in the chest. It became quite severe during a period of 6 weeks and was aggravated by motion and deep respiration. Slight fever (99.2°F) was present. The skin was pale and suggested anemia, which was confirmed by examination of the blood, the red-cell count being 2,610,000 and the hemoglobin 45 per cent. Leukopenia was present, the number of leukocytes varying between 1500 and 5540 per cubic millimeter and the percentage of neutrophils between 4 and 54. The lymphocytes, largely normal in appearance, were the most numerous leukocytes in the majority of smears. At times occasional immature cells of the lymphoblastic type were found. The leukopenic blood picture persisted essentially unchanged for 6 months, when the total number of leukocytes began to increase and reached a maximum of 163,200 within 2 weeks, with a differential count typical of lymphatic leukemia. The patient died on August 20, 1942, approximately 9 months after the onset of symptoms. Autopsy confirmed the diagnosis of lymphatic leukemia.

This case is intentionally omitted from the group of 8 cases of leukemia occurring in radiologists, because the notice of this patient's death gave no indication that he had been exposed to radiation. If his case were included in the radiologic group, the percentage of leukemic deaths therein would be increased to 4.3, and the percentage in the non-radiologic group, in which his case was included, would be slightly lower, thus accentuating the difference between them.

The fact that the patient was a dermatologist suggested a separate estimation of the incidence of leukemia in physicians practicing that specialty. During the ten years covered by the study, 60 physicians listed as dermatologists died. Two of them, including the one reported in this article, died of leukemia, giving a percentage of 3.3. This approaches the incidence in the radiologic group, but the number of cases is too small to be of statistical significance.

SUMMARY

A statistical study of 34,626 obituary notices in the *Journal of the American Medical Association*, covering the ten-year period from 1935 to 1944, reveals that the incidence of leukemia among 205 physicians listed as radiologists was 3.9 per cent, which is more than eight times as great as the incidence (0.44 per cent) among those not listed as radiologists.

This marked difference is substantial evidence that exposure to radiation is a potential cause of leukemia.

A case of lymphatic leukemia in a dermatologist who failed to take adequate precautionary measures against radiologic exposure is reported.

believed that fresh vegetables, particularly the green leafy vegetables, are especially rich sources of carotene for the human dietary. In their determination of pure carotene in green vegetables, Fraps, Meinke and Kemmerer¹⁰ found that green string beans contained 0.03 mg of carotene per 100 gm, beet tops 3.2 mg, sweet potatoes 4.5 to 5.7 mg, and carrots 4.5 to 8.4 mg. Zimmerman, Tressler and Maynard¹¹ report from a study of carotene in fresh and frozen vegetables that bush lima beans contain 0.24 mg per 100 gm, spinach 0.46 mg, asparagus 0.70 mg, and broccoli 1.0 mg. Unfortunately, there is likely to be a serious loss of carotene from commercial vegetables after they are harvested, particularly if they are exposed to summer temperatures in stores or on roadside stands for a considerable period of time.

Since milk is generally considered to be a rich source of riboflavin, it is interesting to compare it and the ice cream under discussion. In studies conducted on milk produced by different breeds of cows in various stages of lactation and fed a variety of rations, Snell and Strong,¹² Hand and Sharp,¹³ Houston, Kon and Thompson,¹⁴ Johnson, Maynard and Loosli,¹⁵ Holmes, Jones, Wertz, Esselen and McKey¹⁶ and other investigators found that the riboflavin content of milk varied from 0.06 to 0.34 mg per 100 gm, with an average value of less than 0.20 mg. Thus, on a weight basis, the ice cream under consideration is a richer source of riboflavin than is average milk, but ice cream is sold on a volume basis,—that is, by the pint or quart,—and because of the large amount of air that is incorporated, it contains much less riboflavin than does an equal volume of milk.

Eggs are considered one of the richest food sources of riboflavin. Engel, Phillips and Halpin¹⁷ found from 0.064 mg to 0.700 mg of riboflavin per 100 gm of albumin, depending on the riboflavin content of the hens' ration. Norris and Bauernfeind¹⁸ also found that the ration influenced the amount of riboflavin in eggs, for fresh eggs from six flocks fed egg mash contained 0.207 mg per 100 gm, whereas those from five flocks fed breeder mash contained 0.247 mg. Snell and Quarles¹⁹ report that whole, white leghorn eggs contain 0.200 mg of riboflavin per 100 gm. It may be concluded from these and other studies that commercial whole eggs contain about 0.20 mg of riboflavin per 100 gm, and thus are not so rich in this vitamin as is the ice cream under discussion.

According to Cheldelin and Williams²⁰ such common foods as beef round, pork loin, veal chop, leg of lamb, mutton shoulder, chicken leg and oysters contain about the same amount of riboflavin as was found in the ice cream under discussion, but these authors found much less riboflavin in whole-wheat bread, chicken breast, salmon, dried lima beans, cabbage and carrots, which are widely used foods. Hodson²¹ studied the riboflavin content of about

fifty fruits and vegetables. Of these only one, broccoli, approached ice cream in riboflavin value, and only six or eight of the others contained half as much riboflavin. Thus, one may conclude from this and other studies that the ice cream under consideration compared favorably with practically all other foods as a source of riboflavin for the human dietary.

SUMMARY

It has been estimated that the retail value of the ice cream consumed in this country annually is about one fourth that of milk and over twice that of eggs, apples or potatoes.

Samples of coffee, maple and vanilla ice cream, manufactured under plant conditions were assayed for carotene, riboflavin and ascorbic acid. The coffee, maple and vanilla ice cream contained 0.09 mg, 0.12 mg and 0.09 mg of carotene and 0.27 mg, 0.26 mg and 0.26 mg of riboflavin per 100 gm, respectively. No ascorbic acid was found, probably because of the large amount of air incorporated in commercial ice cream to increase its bulk.

Comparison of these ice creams with numerous widely used foods shows them to be excellent sources of carotene and riboflavin for the human dietary. The nutritive value of ice cream, however, varies with the nature and amount of the ingredients used and the process of manufacture.

cream was extracted for one hour with 50 cc of acetone-sulfuric acid solution (3 parts acetone to 1 part of 1 ON sulfuric acid). After extraction acetone was added to 60 cc (the original volume), and 6.5 per cent trisodium phosphate solution was added until the reaction of the mixture was pH 4.5. Sufficient distilled water was added to make 200 cc. Fifty cubic centimeters of subnatant liquid was withdrawn, and to this there was added 7 to 10 drops of 4 per cent potassium permanganate solution and sufficient 1 per cent hydrogen peroxide to decolorize. The volume was made up to 100 cc, and the solution was filtered. Three 20-cc aliquots, designated as A, B and C, were withdrawn. One cubic centimeter of water was added to aliquot A, 1 cubic centimeter of standard riboflavin solution (0.025 mg per cubic centimeter) to aliquot B and 1 cc of water and a few crystals of sodium hydrosulphite to aliquot C. Ten cubic centimeters of each aliquot was transferred to cuvettes and read in the spectrophotometer, as described by Holmes, Jones, Wertz and Kuzmeski.⁴

Reduced Ascorbic Acid

The ascorbic acid content of the ice cream was determined by a modification of the method of Holmes, Tripp, Woelffer and Satterfield.⁵ Twenty-five grams of ice cream was weighed into a tared centrifuge tube, intimately mixed with 25 cc of a mixture of equal parts of 5 per cent metaphosphoric acid and 10 per cent acetic acid, and centrifuged for ten minutes. The mixture was filtered and repeatedly washed with 5 per cent metaphosphoric acid. Approximately 50 cc of the filtrate was transferred to a 125-cc Erlenmeyer flask, 0.5 gm of 300-mesh Bentonite was added, and the mixture was shaken vigorously for one minute, allowed to settle and filtered. Ten-cubic centimeter portions of the clear, colorless filtrate were titrated with a standard 2-6 dichlorophenolindophenol dye solution.

RESULTS

Ten samples of coffee, of maple and of vanilla ice cream were assayed for carotene, riboflavin and reduced ascorbic acid. The results were quite uniform for all three flavors. The extreme values for carotene and riboflavin for each of the three flavors are reported below, but since close agreement was obtained for the different samples of the flavors, only the average values are reported in Table 1.

The carotene content of the coffee ice cream varied from 0.09 to 0.10 mg per 100 gm, with an average of 0.09 mg. The amount of carotene in the maple ice cream ranged from 0.11 to 0.12 mg per 100 gm, with an average of 0.12 mg. The vanilla ice cream contained from 0.09 to 0.10 mg per 100 gm, with an average of 0.09 mg. Thus, the average values for the carotene content of coffee and of

vanilla ice cream were identical, but that of maple ice cream was somewhat higher.

The riboflavin content of the ice cream was virtually uniform for each flavor. The amount in the coffee ice cream varied from 0.25 to 0.29 mg per 100 gm, with an average of 0.27 mg. The maple

TABLE 1 Vitamin Content of Ice Cream *

EXPERIMENT No	CAROTENE	RIBOFLAVIN	REDUCED ASCORBIC ACID
	mg / 100 gm	mg / 100 gm	mg / 100 gm
1	0.10	0.27	0.00
2	0.10	0.26	0.00
3	0.11	0.26	0.00
4	0.10	0.27	0.00
5	0.10	0.28	0.00
6	0.10	0.26	0.00
7	0.11	0.26	0.00
8	0.10	0.26	0.00
9	0.10	0.25	0.00
10	0.10	0.27	0.00
Averages	0.10	0.26	0.00

*Averages for ten samples of coffee, maple and vanilla ice cream.

ice cream contained from 0.24 to 0.28 mg per 100 gm, with an average of 0.26 mg. The amount of riboflavin in the vanilla ice cream ranged from 0.25 to 0.29 mg per 100 gm, with an average of 0.26 mg.

The reduced ascorbic acid was determined for ten samples of each of the three flavors. Only five or six of the thirty samples showed even a detectable trace of reduced ascorbic acid. These results were not unexpected, however, since, as stated above, nearly half the volume of the finished ice cream consisted of air that had been whipped into it during the freezing process. The air dispersed throughout the ice cream obviously favored rapid oxidation of the reduced ascorbic acid.

Obviously, the amount of carotene, riboflavin and reduced ascorbic acid in any ice cream is influenced by the type and amount of the materials used in its manufacture, the procedure used for preparing it and the conditions under which it is stored during the interval between manufacture and consumption. Since these factors vary widely with conditions and localities, the nutritive value of both homemade and commercial ice cream is quite variable.

DISCUSSION

It is interesting to compare the amount of carotene found in the three flavors of ice cream — 0.09 mg, 0.12 mg and 0.09 mg per 100 gm — with that found in some other common foods. The amount in fresh whole milk is apparently quite variable, for Tuzson⁶ found 0.003 mg per 100 gm, and Guggenheim⁷ reported 0.028 mg, 0.017 mg and 0.010 mg per 100 gm, respectively, for milk produced in hill, valley and urban areas of Palestine. Olson, Hegsted and Peterson⁸ state that fresh whole milk contains 0.021 mg of carotene per 100 gm, and Dornbush, Peterson and Olson⁹ found 0.011 mg of carotene per 100 gm in March milk and 0.035 mg in September market milk. From these and other studies it is evident that the three ice creams used in this study were a much richer source of carotene than is whole milk. It is generally

believed that fresh vegetables, particularly the green leafy vegetables, are especially rich sources of carotene for the human dietary. In their determination of pure carotene in green vegetables, Fraps, Meinke and Kemmerer¹⁰ found that green string beans contained 0.03 mg of carotene per 100 gm, beet tops 3.2 mg, sweet potatoes 4.5 to 5.7 mg, and carrots 4.5 to 8.4 mg. Zimmerman, Tressler and Maynard¹¹ report from a study of carotene in fresh and frozen vegetables that bush lima beans contain 0.24 mg per 100 gm, spinach 0.46 mg, asparagus 0.70 mg, and broccoli 1.0 mg. Unfortunately, there is likely to be a serious loss of carotene from commercial vegetables after they are harvested, particularly if they are exposed to summer temperatures in stores or on roadside stands for a considerable period of time.

Since milk is generally considered to be a rich source of riboflavin, it is interesting to compare it and the ice cream under discussion. In studies conducted on milk produced by different breeds of cows in various stages of lactation and fed a variety of rations, Snell and Strong,¹² Hand and Sharp,¹³ Houston, Kon and Thompson,¹⁴ Johnson, Maynard and Loosli,¹⁵ Holmes, Jones, Wertz, Esselen and McKey¹⁶ and other investigators found that the riboflavin content of milk varied from 0.06 to 0.34 mg per 100 gm, with an average value of less than 0.20 mg. Thus, on a weight basis, the ice cream under consideration is a richer source of riboflavin than is average milk, but ice cream is sold on a volume basis,—that is, by the pint or quart,—and because of the large amount of air that is incorporated, it contains much less riboflavin than does an equal volume of milk.

Eggs are considered one of the richest food sources of riboflavin. Engel, Phillips and Halpin¹⁷ found from 0.064 mg to 0.700 mg of riboflavin per 100 gm of albumin, depending on the riboflavin content of the hens' ration. Norris and Bauernfeind¹⁸ also found that the ration influenced the amount of riboflavin in eggs, for fresh eggs from six flocks fed egg mash contained 0.207 mg per 100 gm, whereas those from five flocks fed breeder mash contained 0.247 mg. Snell and Quarles¹⁹ report that whole, white leghorn eggs contain 0.200 mg of riboflavin per 100 gm. It may be concluded from these and other studies that commercial whole eggs contain about 0.20 mg of riboflavin per 100 gm, and thus are not so rich in this vitamin as is the ice cream under discussion.

According to Cheldelin and Williams²⁰ such common foods as beef round, pork loin, veal chop, leg of lamb, mutton shoulder, chicken leg and oysters contain about the same amount of riboflavin as was found in the ice cream under discussion, but these authors found much less riboflavin in whole-wheat bread, chicken breast, salmon, dried lima beans, cabbage and carrots, which are widely used foods. Hodson²¹ studied the riboflavin content of about

fifty fruits and vegetables. Of these only one, broccoli, approached ice cream in riboflavin value, and only six or eight of the others contained half as much riboflavin. Thus, one may conclude from this and other studies that the ice cream under consideration compared favorably with practically all other foods as a source of riboflavin for the human dietary.

SUMMARY

It has been estimated that the retail value of the ice cream consumed in this country annually is about one fourth that of milk and over twice that of eggs, apples or potatoes.

Samples of coffee, maple and vanilla ice cream, manufactured under plant conditions were assayed for carotene, riboflavin and ascorbic acid. The coffee, maple and vanilla ice cream contained 0.09 mg, 0.12 mg and 0.09 mg of carotene and 0.27 mg, 0.26 mg and 0.26 mg of riboflavin per 100 gm, respectively. No ascorbic acid was found, probably because of the large amount of air incorporated in commercial ice cream to increase its bulk.

Comparison of these ice creams with numerous widely used foods shows them to be excellent sources of carotene and riboflavin for the human dietary. The nutritive value of ice cream, however, varies with the nature and amount of the ingredients used and the process of manufacture.

CLINICAL NOTE

SPOROTRICHOSIS*

REPORT OF A CASE

MAJOR SPENCER C FLO, M C, A U S, AND
CAPTAIN PAUL E SMITH, M C, A U S

SPOROTRICHOSIS is seldom seen in the United States and is easily confused with a number of other diseases. Strictly speaking, it presents a dermatologic problem, but the surgeon may encounter the disease in its early stages when it resembles a local infection. As it progresses and

The responsible organism is *Sporotrichum schenckii*, a fungus probably acquired in this country through contact with a plant, such as the barberry shrub, a carnation or sphagnum moss. A break in the skin seems necessary as a portal of entry, since in most of the reported cases there is a history of an open lesion while the patient was in contact with the plant. The incubation period ranges from three days to three weeks. The primary lesion appears as a deep pustule at the site of entry, which may either become chancroid in character, with induration, softening and abscess formation, or take the form of an indolent ulcer. Later the regional lymph channels become involved, causing a lymphangitis, with nodulations along the channels simulating enlarged lymph nodes, but the nodes themselves are not involved. The skin surrounding these nodules is usually reddish purple. The nodules

FIGURE 1 Photograph of the Primary Lesion

This occurred on the inner aspect of the thumb, with nodulations extending upward on forearm

lymphatic invasion occurs, it becomes evident that one is dealing with a granuloma. For this reason, one should recall the possibility of sporotrichosis when considering a skin lesion that may be due to syphilis, tuberculosis, pyoderma, coccidiomycosis, actinomycosis or tularemia.

Sporotrichosis was first described as a pathogenic entity by Schenck in 1898. Since then, about 200 cases have been reported in the United States. Five of these were from New York State, and most of the others were from the Mississippi Valley.

*From the Surgical Service, Station Hospital, Bolling Field D C.

frequently break down, appearing like the original lesion. This is the most frequent form of the disease; it is described in textbooks as the "localized lymphangitic type." Constitutional symptoms are rare, and the lesions are usually painless. Some authors believe that surgery is contraindicated, but others have shown that scar formation can be greatly reduced by open drainage.

There are four other types of the disease—disseminating subcutaneous, disseminating ulcerative, epidermal and systemic. The disseminating subcutaneous type is the same as the local one except

that the lesions are scattered over the entire body without following any pathway, suggesting an invasion of the blood stream. The disseminating ulcerating type is likewise the same except for much earlier ulceration. The epidermal type involves only the skin but if these local lesions remain untreated, the deeper structures may become involved. The systemic type affects the bones, joints and muscles and is becoming more widely recognized as the causative factor in many obscure pulmonary lesions. In this phase the outlook is serious but the localized lesions readily respond to potassium iodide therapy.

The fungus is extremely difficult to find by direct smear, but Lawless suggests, as a quick method of diagnosis while awaiting the result of cultures,

to admission the lesion on the thumb had been incised. At no time had the patient felt ill or had a fever, and except for the local lesions he appeared well. On the inner aspect of the left thumb toward the flexor surface there were several deep pustules about the size of the head of a match. Around this area the skin was thin and blue (Fig 1). Along the volar surface of the forearm were many slightly tender nodules that felt like enlarged lymph nodes. There was no involvement of the axillary nodes. The temperature, pulse and respirations were normal and remained so throughout hospitalization. Urinalysis and a Wassermann test were negative. The white-cell count was 7200 with 79 per cent neutrophils, 18 per cent lymphocytes, 1 per cent mononuclear cells and 2 per cent basophils. The red-cell count was 4,750,000, and the hemoglobin 15.5 gm.

One of the pustules was opened, and a thin milky fluid exuded, a stained smear of which was negative for ordinary bacteria. Further questioning brought out the fact that 5 days before the appearance of the primary lesion the patient had been hunting rabbits, which suggested tularemia. At that time the lesions took on the characteristics of a granuloma; the nodules began to break down, and the surrounding

FIGURE 2 Photograph of Lesions at a Later Stage

The nodulations ran along the volar aspect of the arm and showed characteristic ulceration and suppuration. They involved only the distal third of the forearm.

adding a drop of Unna-Pappenheim's methyl green-pyronin stain to a drop of pus, after which the fungus can frequently be found by direct examination. Culture is the only definite method of diagnosis and is usually reliable. Pathological examination of tissue is not helpful, since the histologic picture resembles that of all the granulomas. Agglutination and cutaneous tests are of equivocal value.

CASE REPORT

A 41-year-old captain was admitted to the station hospital on December 2, 1944, complaining of an infection of the left thumb, with "streaks and lumps" running up the arm. He had been on a course of sulfadiazine and 100,000 units of penicillin, as well as hot compresses to the thumb. Prior

to admission the lesion on the thumb had been incised. At no time had the patient felt ill or had a fever, and except for the local lesions he appeared well. On the inner aspect of the left thumb toward the flexor surface there were several deep pustules about the size of the head of a match. Around this area the skin was thin and blue (Fig 1). Along the volar surface of the forearm were many slightly tender nodules that felt like enlarged lymph nodes. There was no involvement of the axillary nodes. The temperature, pulse and respirations were normal and remained so throughout hospitalization. Urinalysis and a Wassermann test were negative. The white-cell count was 7200 with 79 per cent neutrophils, 18 per cent lymphocytes, 1 per cent mononuclear cells and 2 per cent basophils. The red-cell count was 4,750,000, and the hemoglobin 15.5 gm.

One of the pustules was opened, and a thin milky fluid exuded, a stained smear of which was negative for ordinary bacteria. Further questioning brought out the fact that 5 days before the appearance of the primary lesion the patient had been hunting rabbits, which suggested tularemia. At that time the lesions took on the characteristics of a granuloma; the nodules began to break down, and the surrounding

SUMMARY

A case of sporotrichosis is reported, primarily for its surgical interest, since in the early stages the disease often presents itself as an ordinary infection. Early diagnosis is important, since treatment

require five to seven days before showing growth

SYMPOSIUM ON MEDICAL SOCIOLOGY

PROBLEMS IN THE DISTRIBUTION OF MEDICAL CARE*

DEAN A. CLARK, M.D.†

IT IS no accident that the Harvard Medical School has decided to hold these lectures on medical sociology. Never before has there been such widespread interest and activity in the social aspects of medicine among all groups of people — not only medical students and practicing physicians but farmers, members of labor organizations, businessmen and government officials. Ten years ago it would not have occurred to anyone to have such a lecture series, but today it seems the most natural thing imaginable.

Indeed, the question of how better to distribute medical service is constantly present. Among groups of physicians, for example, the New York Academy of Medicine has been holding a series of fifty or more weekly meetings devoted to "Medicine and the Changing Order." Then too, one can scarcely pick up an issue of a newspaper — the *New York Times*, for instance — without finding an article or perhaps an editorial dealing with the subject. Only last month a major article in *Fortune* was devoted to it, and radio forums touch on it nearly every week.

One is also reminded of the general interest in these matters by the polls of public opinion that have been appearing with increasing frequency. Although these polls differ considerably from one another in detail, all without exception show that the majority of the people believe that some change is necessary in the ways in which medical care is being distributed. A poll conducted by the American Medical Association among medical officers of the Army and Navy indicated that most of those who replied were unwilling to return to the individual practice of medicine on a fee-for-service basis.

Another constant problem is the fact that some 12,000,000 Americans now serving in the armed forces will, as veterans, have enduring rights to hospital care for both service-connected and non-service-connected disabilities for the rest of their lives, at the expense of the federal government. It is difficult to say, moreover, just what the effect will be on the millions of soldiers and sailors — and their thousands of physicians — of having received or furnished comprehensive medical service of the highest character for three years or so without the payment of any fees at all.

Besides the purely military medical services, the war has brought a number of new activities in medicine affecting civilians, and these too are bound

to affect the future of medical practice in this country. Think, for example, of the aid given to medical students by the Army and Navy. For the first time, men who wished to study medicine have been enabled through this aid to do so without regard to their financial status. Similar opportunities in nursing have been offered by the Cadet Nurse Corps. In the realm of research, the Office of Scientific Research Development, through its Committee on Medical Research, has financed an incredible amount of important scientific work in medical schools, hospitals and laboratories. The Emergency Maternal and Infant Care Program supervised by the United States Children's Bureau has paid, with federal funds granted to the states, for the care of the wives and infants of hundreds of thousands of enlisted men. It is impossible to believe that some of the benefits of these wartime activities will not be continued in one form or another after the war is over.

Other indications of the desire for improved distribution of the benefits of modern medicine are to be found in the public actions of various influential persons and groups. Less than a month ago, for example, Governor Warren, of California, stated his intention of supporting compulsory health insurance in that state. Mayor La Guardia, of New York City, has announced the initiation of a plan to provide 1,000,000 residents of that city with medical care on a prepayment group-practice basis. The American Public Health Association has recently gone on record as favoring a nationwide system of medical care for all people, supported by compulsory insurance, general taxation or a combination of the two. In another statement, some thirty physicians and laymen have urged national action to furnish complete medical care of high quality to the American people. Included in the group, incidentally, was a physician who is a recent president of the American Hospital Association and is now chairman of the Commission on Medical Care appointed by Governor Dewey, of New York. Another physician-signer of the statement has recently served two terms as president of the Massachusetts Medical Society.

Finally, of course, there are the prospects of official governmental action in this and other countries. Here there is the much discussed Wagner-Murray-Dingell Bill, in Great Britain there is the Churchill government's "White Paper" proposing a national health service, in Canada, several years of study have yielded a national health bill that includes compulsory insurance, which has been approved in principle by the Canadian Medical

*This is the second of a series of nine lectures on medical sociology given weekly at Harvard Medical School during January-February and March 1945. They were sponsored by the Department of Preventive Medicine and were primarily intended for third year students. These articles will temporarily replace the reports "Medical Progress."

†Senior surgeon United States Public Health Service, medical director Health Insurance Plan of Greater New York (on leave of absence).

Association All these proposals are sweeping in character, and they indicate the trend among important sectors of legislative opinion

So there can be little doubt that this series of lectures is indeed timely. All this interest in the better distribution of medical and health services is certainly noteworthy, but one may well ask why it has come about. Is it purely accidental that so many people are concerned about this subject, or has the feeling been aroused by a small, highly vocal minority? Or are there, perhaps, deeper reasons for it? Perhaps the title of this lecture should be changed from "Problems in the Distribution of Medical Care" to "Is There a Problem in the Distribution of Medical Care?" with the subtitle, "If So, What Is the Nature of the Problem?"

First, is there really any problem? With the lowest over-all national death rate in its history and one of the lowest in the world, should not the United States be perfectly content to let well enough alone? This is a point of view one often hears expressed. But the over-all death rate is a sweeping average and, as every science student knows, one must look behind an average to see what makes it up. Here are a few examples of disparities in death rates.

In 1941, when the national death rate was 10.3 per 1000 for Whites, it was 13.7 for Negroes. In 1942, the death rate for tuberculosis for all people was 42.2 per 100,000. For Whites alone in that year it was 34, but for Negroes, it was 112, and for Indians 230. When the death rate for infants under one year of age — often considered the most accurate index of health — was 45 per 1000 live births for all people in 1941, it was only 31 in Connecticut, but in New Mexico it was 95.

It is easy to see from these examples that over-all death rates do not tell the whole story. But it may further be asked what information even the most refined figures on death rates give about people's health and their need for medical care. Obviously, figures on deaths tell practically nothing about the state of positive health, since they give no indication how many of the population are really well nourished, full of physical vigor and emotionally well adjusted. What is more, death rates do not even reveal much about the prevalence and duration of disease and disability and therefore about the need for medical care.

Indeed, a lower death rate may well be accompanied by a higher rate of disability, paradoxical as this may sound. For instance, much of the dramatic fall in the national death rate in this country has been due to control of communicable disease, especially diseases of childhood. As everyone knows, people live longer and there are proportionately more elderly persons than there used to be. The population is aging. But of course elderly persons are far more susceptible than are young ones to chronic diseases such as arthritis, cardiovascular-renal disease and diabetes, which

result in much longer disability than do most diseases of childhood. As another example, a few years ago a man might come down with an overwhelming lobar pneumonia and be dead in three days in spite of the best treatment available. Today, with the sulfonamide drugs and penicillin, such a patient might well be cured, but he would be disabled for at least thirty days — ten times the disability, ten times the need for medical and nursing care, but a live patient and a decreased death rate.

Such figures on the incidence and duration of disease and disability as exist cannot be compared with those of a generation ago, because at that time such surveys had not been made. But the examples given above at least make it clear that lowered death rates do not tell much about the state of the Nation's health and do not imply that there is less disability or less need for medical care than there was in earlier years. It seems quite probable, in fact, that the country needs more medical care than ever before, but the kind required is somewhat different. There is relatively less need in medical practice for immediate and dramatic life-saving measures, there is need for more preventive service, more care of chronic illness and more attention to the emotional, psychological and social aspects of illness. This changing pattern of medical practice is not always fully realized — or liked — by physicians, but there is no doubt that it is taking place.

It therefore seems reasonable to conclude that there is indeed a problem in the distribution of medical care. What, then, is the nature of the problem? Is it primarily a lack of adequate scientific knowledge? Obviously, this need exists and must be met, but no one can look at the present situation and not agree, also, that the knowledge now at hand is not being used effectively. The venereal diseases, for instance, can be wiped out today, but the country is still, in spite of much excellent work, a long way from this goal. So that the present problem in medicine is not simply a need for more knowledge.

Is the need principally one for more and better facilities and trained personnel? Of course this lack does exist, but in the case of physicians, for instance, once they have been released from the armed forces the Nation will not be so badly off so far as sheer numbers are concerned. The real question is whether they are available to the people who require their services. Much the same thing is true of hospital beds and trained nurses. Certainly more of them are needed, but one must also stop and ask whether the best use is being made of those now at hand. In some fields, it is true that there are absolute numerical shortages. For instance, there are not nearly enough dentists, public-health nurses, psychiatrists or medical and psychiatric social workers. Even with these groups, using what there is to the best advantage would make a

vast difference. In short, lack of facilities and trained personnel is by no means the heart of the problem.

Is the problem perhaps lack of money? The people of the United States are spending more than \$4 000,000,000 a year for health services including all funds spent by private patients, industry, charities and foundations and government agencies. To be sure, more money could be used advantageously, but many health and medical services are already being supported with great generosity. In fact, if all the funds now expended were used more systematically and distributed more equitably, the present amount would not be far short of adequate. Lack of funds is not, therefore, the entire basis of the difficulty.

If the weaknesses in the present distribution of health and medical services are not due solely to lack of scientific knowledge, facilities, trained personnel or funds, what is the real nature of the problem? There are several ways of describing it — or, it might be said, several elements in it. First, because it is perhaps the element recently most talked about, let us consider the inequitable distribution of personnel and facilities. Before the war there was one physician to 750 people in the United States, but in New York State there was one to 500 people, whereas in Mississippi there was one to 1500. Similarly with general hospital beds, there was one to 250 persons for the country as a whole, with one to 200 in New York State and one to 650 in Mississippi. And, it should be said, differences between communities within each state were as great as those between states. Even greater inequities exist in the distribution of nurses and dentists.

There can be little doubt that this uneven distribution is fundamentally the result of general economic conditions. In 1938, for example, counties with an annual per capita income of more than \$600 had eight times as many physicians relative to the population as did counties with one of less than \$100. Another factor is that physicians do not want to practice in rural areas. In 1938, even the wealthiest group of rural counties had 30 per cent fewer physicians relative to the population than did urban areas of the same per capita income. A third factor is the presence or absence of hospital and diagnostic facilities. Among counties with an annual per capita income of \$300 or less, those with no general-hospital beds had 60 per cent fewer physicians relative to the population, than did those with reasonably adequate general-hospital facilities. During the war, the inequities of distribution have grown worse. The result is that by the end of 1943 almost one third of all the counties in the United States had more than 3000 persons per physician.

The situation has been summed up in another way by Davis¹

Communities of under 5000 population had 48 per cent of the population of the United States in 1929, but only 30 per cent of the physicians, and these physicians received only 18 per cent of the total gross income of all privately practicing physicians. Cities of between 5000 and 100,000 population had 23 per cent of the people and 26 per cent of the physicians, and these physicians obtained 28 per cent of the total physicians' income.

Cities of 100,000 and over had 29 per cent of the population and 44 per cent of the physicians, and these physicians received 54 per cent of the total gross income.

Another major element of the problem is the present pattern of payment for medical care. The provision of such care may be said to depend on two factors: medical need and medical demand. Medical need is composed of the actual physical and emotional requirements of a patient for a physician or for other services. This need can, of course, be determined only professionally — that is, by a physician through a medical history, a physical examination, laboratory tests and so on. But medical demand is quite another matter, and it does not necessarily correspond at all with the medical need. This demand is composed of at least three elements. The first of these is the psychological and educational background of the patient. Is he afraid of all doctors or is he perhaps overanxious to use them? Does he know how and when to make use of available medical services? The second element is the physical presence or absence of medical personnel and facilities. There is always less demand on physicians or hospitals by patients who have to travel far to reach them than by those nearer at hand. The third element is the economic status of the patient. Can he afford to pay the physician's or hospital's bill, or is he afraid he may be unable to do so and therefore hesitant to seek medical aid? Demand is affected, too, by whether the method of payment is that of fees for service which acts in many cases as a barrier to obtaining service, or by periodic prepayment or insurance, which requires no further payment at the time of receiving service and therefore usually increases medical demand.

It is of course medical demand that largely determines the distribution of medical personnel and facilities and the receipt of medical care. It should include general social, educational and economic conditions, as well as physiological needs. These conditions are clearly beyond the power of the medical profession alone to change. The conclusion inescapably follows that the profession alone cannot appreciably alter medical demand and therefore cannot hope to influence or affect greatly the distribution of medical care. Since the latter ultimately depends on general economic and social factors, it clearly can be much altered only by general public action. The medical profession can, however, play an important role in assisting and guiding such public action into constructive and fruitful channels.

The principal facts concerning payment for and receipt of medical care today may be briefly summarized as follows. Families with incomes of less than \$1200 a year pay on the average \$43 a year per family for medical care. The same group annually receives 1900 physicians' house, office and clinic calls per 1000 persons. Forty-seven per cent of such persons receive no medical care in any one year, but this group has sixteen days of disability per capita annually. Those earning from \$2000 to \$3000 pay \$90 a year per family for medical care and receive annually 2300 physicians' calls per 1000 persons. Only 37 per cent receive no medical attention in a year, and the group has only six days of disability per person per year. The group with incomes of \$10,000 pays \$500 a year per family for medical care and receives annually 4700 physicians' calls per 1000 persons. Only 14 per cent receive no care each year, and annual days of disability are less than six per person.

It thus appeared that the lower the income group, the more days of disability and the fewer physicians' calls. The heart of the major problem is illustrated by these facts. In general, it is safe to say that, except for days of hospital care in urban centers with well developed public-hospital systems, the least care gets to the people who need it most, that is, those who have the most illnesses and the most days of disability but the least money to pay for medical care. Medical demand certainly does not follow medical need.

The problem of payment for medical care divides into two parts. First, there is what might be called "absolute inability" to pay the full cost of care, whatever the method of payment. Among families with incomes below a certain level, say \$1200 a year, the costs of medical care of reasonably good quality obviously cannot be met. Even in the prosperous year 1943, about one third of the country's population fell into this group. Persons in the lower economic levels also have larger families and more sickness than have the well-to-do. This combination of circumstances makes it totally impossible for these people to pay the full costs by themselves, even on a prepayment basis, and what they can pay must be supplemented from other sources.

It is sometimes suggested that people might be induced by educational measures to increase the amount they would be willing to spend for medical care. The proportion of family income expended for automobiles, washing machines, moving pictures, cosmetics and so forth has certainly come up sharply in recent years. Why not the same thing for health services? Possibly it could be done, but health expenditures have to compete with other human wants. Besides, people buy automobiles, lipsticks and washing machines because they *want* them — and nobody wants to have to see a doctor or a dentist.

In addition to this absolute inability to pay the full costs of medical care, there is the even more important second part of the problem of payment — namely, relative inability to pay. This affects not merely families at the bottom levels of income but those of all economic levels except perhaps the top 5 per cent. This problem arises from the fact that the incidence and severity of illness are unpredictable for the individual, yet, under the fee-for-service system, he is obliged to pay only when illness occurs. Thus, with the traditional method of payment the heaviest burden falls, in any one year, on the few persons unfortunate enough to be ill, and this burden strikes just at the time when, for the wage-earner, his income is cut off — namely, when he is ill.

For instance, 10 per cent of all the families in the population pay in a given year 41 per cent of the costs of medical care for the whole population and thirty-two per cent pay 41 per cent, so that the remaining 58 per cent pay in any one year only 18 per cent of the total cost of medical care for the country. The incidence of illness is uneven and consequently the distribution of the costs of medical care is also uneven under the fee-for-service system. Many a family with the absolute ability to pay \$150 or more a year for medical care under a planned periodic-prepayment system can suffer serious hardship or even be crushed financially by the enormous costs of a single serious illness, billed all at one time.

Two elements of the problem have so far been considered — the difficulties of the distribution of personnel and facilities and those of payment for service. But what about the organization of medical services? Medicine is no longer a one-man science; it takes diverse skills, expensive equipment and much trained assisting personnel to do a decent job today.

Now, typically, — and it is still typical, — doctors are in individual practice, with considerable duplication and waste of resources. Each has an office, the necessary equipment for x-ray examinations, metabolism tests, electrocardiograms, and laboratory procedures and an office nurse, technician or secretary. He cannot possibly use all these to their full capacity. For example, a friend of mine practicing in a Southern city is proud of his teaching appointments at two medical schools. He also has a private office, with an x-ray machine, metabolic and electrocardiographic apparatus, an adequate laboratory and an office nurse-technician-secretary. Because of his teaching and research and home and hospital calls, he is in his office only two hours a day, three days a week. All the rest of the time his fine equipment and office assistant are virtually idle.

Other evidence of poor organization in the medical services of today is found in the obvious waste of professional skill. Another friend of mine while

a resident in surgery at one of the best teaching hospitals performed one hundred and fifty major operations, most of them with little supervision. His first year in private practice, in a town where he was immediately given a hospital staff appointment and was welcomed by the profession he did only two major operations. This is obviously a serious waste. After a number of years, he may be expected to increase his work to near his capacity, but think of the wasted skill in the intervening years. Also, before he reached this point he may lose much of the technical perfection that was probably at its peak at the close of his year of residency.

Just as important a result of the present inadequate organization of medical services as its waste of resources and professional training is its failure to assure, for the benefit of the patient, the wide diversity of skills essential in good, modern medicine. The physician in individual private practice has to exercise all his ingenuity if he is to obtain for his patients — especially for the less wealthy ones — all the special services that they require. In the first place, specialists and laboratories may simply be unavailable, as in many small towns and rural areas. Even in large cities, general and special physicians and facilities are not related in an orderly manner, and the practitioner may have great difficulty in finding exactly the service that his patient needs. Second, the physician may hesitate to refer patients for consultation or laboratory tests because he knows that they will have to pay for these and it may be hard for them to do so. He may even begin to lose patients if he is too free in advising special work, he begins to get a reputation for "always sending you to a specialist," and patients hesitate to go to him for fear of the added cost. Then, too, patients who go to a specialist sometimes do not return to the original physician at all. For all these reasons, many a physician tries to handle far more than he is competent to, or he may be tempted by offers of split fees from certain specialists. In either event, the patient is the sufferer — he does not receive specialist care solely because of his medical need for it.

The lack of organization is also illustrated by competition rather than co-operation among hospitals. Take the example of four competing hospitals in a small town or in four small towns near one another — a not infrequent occurrence. Each small hospital is trying valiantly, pitifully, to do everything, and of course is unable to do so satisfactorily. A single large hospital could usually provide far better facilities and equipment than any one of the four. Yet consolidation of such rivals is all too often the exception rather than the rule. Planning of hospitals by areas or regions and by special tasks that each can be expected to perform has been strongly advocated for years,

but only recently has any serious attempt been made to carry out such plans.

There have been discussed three elements of the problem of distribution of medical care: the distribution of personnel and facilities, payment for care and organization of services. A fourth element is especially important to a group of medical students — namely, the position of the physician, and the way in which these matters affect his professional and economic opportunities.

This should first be examined from the professional outlook. Medical students are trained in every medical school and teaching hospital in this country under a system of co-operative group medical practice. They learn to apply, for the benefit of their patients, the best available technics and to use the best equipment, with the generous assistance and consultation of their ablest colleagues and teachers. Yet they usually go out into individual private practice, where they are simply unable, even with the best will in the world, to practice the kind of medicine that they learned in their training or, in many cases, to advance their professional skills while they are practicing. The practitioner is "on his own," indeed, and to be so often forces him to practice progressively poorer medicine.

Fortune puts it thus: "Many doctors, on going from the group practice of their internship to a largely solo method of practice, have felt that they have dropped back to a geologically older level of medicine on which they cannot hope to realize their maximum potential for service."

One may think that the professional frustration suffered by large numbers of physicians is compensated for, to a large extent, by their economic rewards, but such is not the case. It is true that few doctors starve, but fewer still get rich. All have necessarily a serious economic problem to face. To begin with, at least \$10,000 or \$12,000 has been spent on the medical education of each. The average net income of all physicians in 1929 was \$5300 a year. By 1934, the average had dropped to \$3300, and by 1941 it had come back to about \$5000. The average net income is certainly higher during the war, but in general the peacetime figures are indicative of the economic status of physicians. The average, however, does not tell the whole story in this instance either. Two thirds of physicians had incomes less than the average — which of course means that a few had extremely large incomes to bring up the average. Half of all physicians in practice were actually earning less than \$4000 net a year in 1929. This is none too much to repay the costs of medical education and to provide for a family and for retirement after sixty-five — few physicians earn much of a livelihood after that age. For every physician who had a net income of \$10,000 or over in 1929, there were two with incomes of less than \$2500.

In general, the physicians with the poorest economic status are young practitioners, general practitioners of any age and rural practitioners of any type and age. The best off are specialists in medium-sized cities who have been seventeen years in practice. It is no wonder that doctors flock into the specialties and into cities. Who would not? One cannot blame them for doing this, because they all have to try to reach a high earning power for at least a few years. The trouble is, of course, that many do not succeed. Statistically speaking, only one in eight of this class will ever have a net income of over \$10,000 a year. Naturally, each is sure that he will be the one. But it is difficult to predict.

Clearly, it is not the physician's fault that his basic economic insecurity obliges him to have a constant and intense interest in his income, to practice where money is and to keep up in the competitive race, sometimes at the expense of his professional skill and integrity. But, regardless of where the fault lies, the fact remains that physicians have a far from satisfactory economic position in the present scheme of things, and their economic position has unfortunate effects on medical practice.

* * *

In summary, there is a problem in the distribution of medical care, the problem is not just a need for more scientific knowledge, facilities, trained personnel or money, however much some or all of these are needed. It has a number of aspects. There is inefficient and inequitable distribution of medical personnel and facilities, present methods of payment for care result in the fact that those with the greatest medical needs, such as the low-income groups, the aged and so forth receive the least care, a large section of the population could

not afford to pay the full cost of all the care they require by any method of payment, another large section cannot pay its full costs without hardship because the incidence and severity of illness are unpredictable, yet under fee-for-service payment the costs must largely be met at the time sickness occurs, there is great economic and professional waste in the present inadequate organization of medical services, the diverse skills and expensive equipment of scientific medicine are poorly integrated to give the best service to the patient, and finally, many physicians have little prospect of either professional satisfaction or economic security in the practice of medicine.

These facts present a serious challenge. There is truly a crisis in American medicine today. In the lectures to come you will hear more about these problems and about the attempts being made, here and abroad, to solve them. Certainly, the open, frank and dispassionate discussion of problems is the healthy means of reaching their solution. This you will have in this lecture series.

There is one more thing to remember. The problems of the distribution of medical and health services are not confined to the medical profession, nor can they be solved by it alone. Health is not the property of physicians but of everyone. These problems are the problems of all the people. To solve them therefore means discussion and action not only by physicians but by the medical profession as a whole, together with those in business, agriculture, labor and government, if we are to look forward with assurance to better health for the American people.

CASE 32021

PRESENTATION OF CASE

First admission A twenty-five-year-old man entered the hospital because albumin had been found in the urine fifteen months previously. He had had no complaints, except for occasional pain over the costovertebral angles.

Physical examination was negative.

The temperature was 98.6°F, the pulse 75, and the respirations 20. The blood pressure was 98 systolic, 78 diastolic.

The red-cell count was 4,460,000, with 80 per cent hemoglobin. The white-cell count was 7400, with 60 per cent neutrophils. The urine was cloudy, yellow and alkaline, and had a specific gravity of 1.014. It gave a ++ test for albumin; the sediment contained 3 red cells, 20 white cells and 2 epithelial cells per high-power field, and amorphous phosphates, triple phosphates and a few bacteria were seen. The nonprotein nitrogen was 20 mg per 100 cc, the serum calcium 10.4 mg, and the phosphorus 3.2 mg. A blood Hinton test was negative. An intravenous pyelogram showed a small area of calcification in the region of the middle calyx of the right kidney; the dye was excreted a little better by the left than by the right kidney. The middle calyx of the right kidney was deformed, and the area of calcification described above was included in the dye. Although both ureters were rather large, there was no definite evidence of hydronephrosis. The urinary bladder was not remarkable.

Cystoscopy showed a slightly reddened bladder. Both ureteral orifices were normal, and catheters were passed to both kidneys without difficulty. A normal flow of slightly hazy urine was obtained from each kidney. Intravenous phenolsulfonephthalein appeared in three minutes from the left kidney and in four minutes from the right. The urine from each kidney showed no cells or organisms and was sterile on culture. The patient was discharged three days after admission.

Second admission (five years later) During the first three years after discharge the patient had three brief episodes of severe pain in the right flank,

which radiated to the right lower quadrant. At the end of that time, several stones were removed from the bladder at another hospital. After this operation he felt well until three months before readmission, when he noticed that he tired easily. He had a sacroiliac ache on exertion, which subsided on rest. He had lost no weight. Three weeks before readmission he passed a stone by urethra.

Physical examination was negative.

The temperature was 98.6°F, the pulse 90, and the respirations 20. The blood pressure was 100 systolic, 60 diastolic.

The hemoglobin was 13.8 gm. The white-cell count was 7900. The urine was cloudy, amber and acid, with a specific gravity of 1.018. It gave a + test for albumin. The urinary sediment contained a rare red cell, 10 white cells and a rare granular cast per high-power field. Culture of the urine revealed on one occasion *Staphylococcus albus*, and on another, colon bacilli and nonhemolytic streptococci. The total phenolsulfonephthalein output was 45 per cent in two hours. The nonprotein nitrogen was 30 mg per 100 cc, the serum protein 5.5 gm, the calcium 10.4 mg, and the phosphorus 3.0 mg. The chloride was 102.1 milliequiv per liter, and the carbon dioxide combining power 26.3 milliequiv. The uric acid was 4.4 mg per 100 cc. An x-ray film of the teeth showed no evidence of apical abscesses or retained roots. An intravenous pyelogram revealed several areas of calcification scattered over both kidney shadows. Intravenous dye appeared promptly in good concentration. There was some distortion of the calyces on both sides, more marked on the left than on the right. The right calyces, pelvis and ureter were dilated, but a definite stone was not visible within the lower ureter.

The patient was discharged improved on the tenth hospital day.

Third admission (one year later) During the year after discharge the patient complained of intermittent, dull, burning pain over both costovertebral angles, which usually appeared in the morning following urination and lasted several hours. He passed several stones. He complained of no frequency, dysuria or bone or joint pain. The serum calcium had remained at about 10.4 mg per 100 cc, and the phosphorus at 3.0 mg. On one occasion, after ten days on a low-calcium diet, the urinary calcium output was 282 mg in twenty-four hours.

Physical examination revealed circumscribed, papular, scaly, erythematous lesions, 1 to 4 cm in diameter, on the inner aspect of the groins, the right lower leg and the forearms.

The temperature was 97°F, the pulse 90, and the respirations 25. The blood pressure was 110 systolic, 70 diastolic.

The hemoglobin was 14.9 gm. The white-cell count was 8100. The urine was light amber and acid, with a specific gravity of 1.010. It contained 3 red cells, 10 white cells and a rare hyaline cast per high-

In general, the physicians with the poorest economic status are young practitioners, general practitioners of any age and rural practitioners of any type and age. The best off are specialists in medium-sized cities who have been seventeen years in practice. It is no wonder that doctors flock into the specialties and into cities. Who would not? One cannot blame them for doing this, because they all have to try to reach a high earning power for at least a few years. The trouble is, of course, that many do not succeed. Statistically speaking, only one in eight of this class will ever have a net income of over \$10,000 a year. Naturally, each is sure that he will be the one. But it is difficult to predict.

Clearly, it is not the physician's fault that his basic economic insecurity obliges him to have a constant and intense interest in his income, to practice where money is and to keep up in the competitive race, sometimes at the expense of his professional skill and integrity. But, regardless of where the fault lies, the fact remains that physicians have a far from satisfactory economic position in the present scheme of things, and their economic position has unfortunate effects on medical practice.

* * *

In summary, there is a problem in the distribution of medical care, the problem is not just a need for more scientific knowledge, facilities, trained personnel or money, however much some or all of these are needed. It has a number of aspects. There is inefficient and inequitable distribution of medical personnel and facilities, present methods of payment for care result in the fact that those with the greatest medical needs, such as the low-income groups, the aged and so forth receive the least care, a large section of the population could

not afford to pay the full cost of all the care they require by any method of payment, another large section cannot pay its full costs without hardship because the incidence and severity of illness are unpredictable, yet under fee-for-service payment the costs must largely be met at the time sickness occurs, there is great economic and professional waste in the present inadequate organization of medical services, the diverse skills and expensive equipment of scientific medicine are poorly integrated to give the best service to the patient, and finally, many physicians have little prospect of either professional satisfaction or economic security in the practice of medicine.

These facts present a serious challenge. There is truly a crisis in American medicine today. In the lectures to come you will hear more about these problems and about the attempts being made, here and abroad, to solve them. Certainly, the open, frank and dispassionate discussion of problems is the healthy means of reaching their solution. This you will have in this lecture series.

There is one more thing to remember. The problems of the distribution of medical and health services are not confined to the medical profession, nor can they be solved by it alone. Health is not the property of physicians but of everyone. These problems are the problems of all the people. To solve them therefore means discussion and action not only by physicians but by the medical profession as a whole, together with those in business, agriculture, labor and government, if we are to look forward with assurance to better health for the American people.

CASE 32021

PRESENTATION OF CASE

First admission. A twenty-five-year-old man entered the hospital because albumin had been found in the urine fifteen months previously. He had had no complaints, except for occasional pain over the costovertebral angles.

Physical examination was negative.

The temperature was 98.6°F, the pulse 75, and the respirations 20. The blood pressure was 98 systolic, 78 diastolic.

The red-cell count was 4,460,000, with 80 per cent hemoglobin. The white-cell count was 7400, with 60 per cent neutrophils. The urine was cloudy, yellow and alkaline, and had a specific gravity of 1.014. It gave a ++ test for albumin, the sediment contained 3 red cells, 20 white cells and 2 epithelial cells per high-power field, and amorphous phosphates, triple phosphates and a few bacteria were seen. The nonprotein nitrogen was 20 mg per 100 cc, the serum calcium 10.4 mg, and the phosphorus 3.2 mg. A blood Hinton test was negative. An intravenous pyelogram showed a small area of calcification in the region of the middle calyx of the right kidney, the dye was excreted a little better by the left than by the right kidney. The middle calyx of the right kidney was deformed, and the area of calcification described above was included in the dye. Although both ureters were rather large, there was no definite evidence of hydronephrosis. The urinary bladder was not remarkable.

Cystoscopy showed a slightly reddened bladder. Both ureteral orifices were normal, and catheters were passed to both kidneys without difficulty. A normal flow of slightly hazy urine was obtained from each kidney. Intravenous phenolsulfonephthalein appeared in three minutes from the left kidney and in four minutes from the right. The urine from each kidney showed no cells or organisms and was sterile on culture. The patient was discharged three days after admission.

Second admission (five years later). During the first three years after discharge the patient had three brief episodes of severe pain in the right flank,

which radiated to the right lower quadrant. At the end of that time, several stones were removed from the bladder at another hospital. After this operation he felt well until three months before readmission, when he noticed that he tired easily. He had a sacroiliac ache on exertion, which subsided on rest. He had lost no weight. Three weeks before readmission he passed a stone by urethra.

Physical examination was negative.

The temperature was 98.6°F, the pulse 90, and the respirations 20. The blood pressure was 100 systolic, 60 diastolic.

The hemoglobin was 13.8 gm. The white-cell count was 7900. The urine was cloudy, amber and acid, with a specific gravity of 1.018. It gave a + test for albumin. The urinary sediment contained a rare red cell, 10 white cells and a rare granular cast per high-power field. Culture of the urine revealed on one occasion *Staphylococcus albus*, and on another, colon bacilli and nonhemolytic streptococci. The total phenolsulfonephthalein output was 45 per cent in two hours. The nonprotein nitrogen was 30 mg per 100 cc, the serum protein 5.5 gm, the calcium 10.4 mg, and the phosphorus 3.0 mg. The chloride was 102.1 milliequiv per liter, and the carbon dioxide combining power 26.3 milliequiv. The uric acid was 4.4 mg per 100 cc. An x-ray film of the teeth showed no evidence of apical abscesses or retained roots. An intravenous pyelogram revealed several areas of calcification scattered over both kidney shadows. Intravenous dye appeared promptly in good concentration. There was some distortion of the calyces on both sides, more marked on the left than on the right. The right calyces, pelvis and ureter were dilated, but a definite stone was not visible within the lower ureter.

The patient was discharged improved on the tenth hospital day.

Third admission (one year later). During the year after discharge the patient complained of intermittent, dull, burning pain over both costovertebral angles, which usually appeared in the morning following urination and lasted several hours. He passed several stones. He complained of no frequency, dysuria or bone or joint pain. The serum calcium had remained at about 10.4 mg per 100 cc, and the phosphorus at 3.0 mg. On one occasion, after ten days on a low-calcium diet, the urinary calcium output was 282 mg in twenty-four hours.

Physical examination revealed circumscribed, papular, scaly, erythematous lesions 1 to 4 cm in diameter, on the inner aspect of the groins, the right lower leg and the forearms.

The temperature was 97°F, the pulse 90, and the respirations 25. The blood pressure was 110 systolic, 70 diastolic.

The hemoglobin was 14.9 gm. The white-cell count was 8100. The urine was light amber and acid, with a specific gravity of 1.010. It contained 3 red cells, 10 white cells and a rare hyaline cast per high-

power field. A urinary culture showed abundant colonies of *Staph albus* on one occasion and was sterile on another. A phenolsulfonephthalein test showed 47 per cent excretion in two hours. The non-protein nitrogen was 30 mg per 100 cc, the total serum protein 7.3 gm, the calcium 10.6 mg, and the phosphorus 2.7 mg. The chloride was 102 milliequiv per liter, and the phosphatase was 6.1 Bodansky units per 100 cc.

Early on the fifth hospital day the patient began to complain of generalized aches and pains, headache and an infrequent, nonproductive cough. During the day, malaise and cough continued and discomfort developed over the sternum and the left upper chest anteriorly. There was some tenderness to percussion over the left anterior chest just below the clavicle. The breath sounds were questionably diminished over this area, without dullness or rales. The abdomen was normal. An x-ray film of the chest was negative. Hemolytic streptococci were cultured from the sputum. The evidences of infection subsided in five days and the patient was discharged.

Fourth admission (two and a half years later). During the period after discharge the patient had had occasional episodes of cloudy urine, he had passed a stone about a year before admission. He complained of no chills, fever, hematuria or renal colic.

Physical examination was negative.

The temperature was 100°F, the pulse 90, and the respirations 20. The blood pressure was 108 systolic, 72 diastolic.

The hemoglobin was 14.3 gm. The white-cell count was 7800. The urinary sediment contained an occasional white cell and epithelial cell. The urine culture showed *Staph albus*. The urinary calcium output was 328 mg in twenty-four hours. A phenolsulphonephthalein test showed 60 per cent excretion in two hours. The nonprotein nitrogen was 31 mg per 100 cc, the total serum protein 6.2 gm, the calcium 9.4 mg, and the phosphorus 2.6 mg. The phosphatase was 4.4 Bodansky units per 100 cc, and the chloride 102 milliequiv per liter. In an x-ray film of the teeth the lamina dura was found to be preserved. A barium swallow showed that the esophagus and trachea were displaced slightly to the left in the upper neck. No definite defects were seen in the esophagus. There was no substernal displacement of the esophagus or trachea. There was a small soft-tissue thickening in the region of the thyroid gland. An intravenous pyelogram revealed many small flecky areas of calcification in the region of all the calyces of both kidneys. The bones showed slight decalcification.

The calyces were normal in shape, size and position.

No stones were seen in the abdomen.

They were promptly in both kidneys.

of the calyces, calyces,

pelvis and ureter were slightly dilated. The bladder shadow was not remarkable.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR JOSEPH AUB: This is an "Albrightian" case, and I am sure that I am going to be educated.

Are there any x-ray films?

DR BENJAMIN CASTLEMAN: We have films, but there is no roentgenologist to interpret them.

DR AUB: There are flecks of calcium in the kidneys, which appear to be in the calyces rather than in the parenchyma. The kidneys themselves do not look large. One can be sure that the calcium is in the calyces because the areas of calcification are obscured by the pyelogram dye. There is some slight decalcification of bone.

We have, then, a man who had been going on for many years with repeated passage of kidney stones. The kind of stones is not mentioned, although I suspect that Dr Albright knew whether they were phosphate, oxalate or uric acid stones.

DR CASTLEMAN: The record states that they showed a large amount of phosphate and a small amount of oxalate.

DR AUB: Since these were phosphate stones, it makes one think, of course, of parathyroid disease. This boy was carefully studied, however, over a long period of time and never had a high blood calcium and had only an occasional relatively low phosphorus. The high calcium output in the urine on two occasions is extremely suggestive of hyperparathyroidism and makes one think that that is the diagnosis. But that is not adequate evidence for me to make this diagnosis. I do not see the soft-tissue mass in the neck in the x-ray films, but it is said to have distorted the trachea and esophagus. But a parathyroid tumor is practically always so soft that it does not, in my experience, shift the esophagus. There is said to have been thickening around the thyroid gland, which is rather suggestive of a thyroid rather than parathyroid adenoma. In favor of hyperparathyroidism, however, are the high calcium output, the two low phosphorus determinations and the slight decalcification. This does not seem sufficient evidence to make a diagnosis of hyperparathyroidism in a patient who repeatedly had a normal blood calcium, often a normal blood phosphorus and a good lamina dura around the teeth, particularly when the disease had been going on for a long time, as judged by the renal calculi. On the contrary, it fits in better, it seems to me, with a renal condition described by Randall,* of Philadelphia, in which calcified areas appear beneath the mucous membrane in the calyces of the kidneys and eventually break through, stones gradually accumulating around these denuded calcified areas. He found that the stones could be composed of

*Randall, A. Initiating lesions of renal calculus. *Surg Gynec & Obst* 64: 201-208, 1937.

phosphate or oxalate or uric acid, depending on the deposition from the urine. With such a diagnosis, this patient would not be placed in the hyperparathyroid group, although I do not believe that the articles published by Randall rule out hyperparathyroidism in his cases.

I am willing to say that the surgeon who operated on this patient looked for a parathyroid tumor. I do not believe that he found it, nor do I believe that he even found large parathyroid glands, because I doubt that this man had enough renal damage to cause parathyroid hyperplasia. I think that he probably had an old pyelonephritis, which may have accentuated the production of stones.

DR EDWARD C REIFENSTEIN: I should like to give Dr Aub some blood chemical determinations that I had in my office notes but that did not get into the hospital record.

DR AUB: One set of values is as follows: calcium, 11.2 mg; phosphorus, 2.8 mg; and phosphatase, 10 Bodansky units. Another is calcium 10.9 mg and phosphorus 3.5 mg, with later a phosphatase of 5.3 units. Still another is calcium 10.3 mg, phosphorus 2.5 mg and phosphatase 5.9 units. These are suggestive of hyperparathyroidism, I admit. I think that a search for overactivity of the parathyroid glands is justified, but if I had operated on this man, I should have looked for a parathyroid tumor without conviction, and I shall end up by saying that I do not believe that they found one.

DR FULLER ALBRIGHT: If one gives a small dose of parathyroid hormone to a normal person, one may get increased calcium in the urine, although the blood calcium may still be normal. Thus, with a moderate degree of hyperparathyroidism, a patient can have a normal blood calcium and still have increased calcium in the urine and kidney stones, such a patient should have a low serum phosphorus, unless there is glomerular damage.

This case discussed by Dr Aub is one of a large group of cases that we see in the Stone Clinic in which it is difficult to rule out a mild primary hyperparathyroidism. These patients show increased calcium in the urine, a low serum phosphorus and a normal or slightly low, occasionally slightly high, serum calcium. We think that these cases are due to pyelonephritis with resulting tubular damage, as a consequence of which the kidneys lose calcium far more readily than normal ones. The sequence of events in this group can be summarized as follows: pyelonephritis, a kidney that lets calcium through more readily than normal, a tendency to a low serum calcium, secondary hyperparathyroidism to meet the tendency to a low calcium, and a low serum phosphorus. One ends up with a normal serum calcium, a low serum phosphorus, a low calcium-phosphate ion product and, hence, a tendency to osteomalacia and a high serum phosphatase, which this man had. You can see that it may be difficult to differentiate this group of cases from

those of primary hyperparathyroidism, which may have secondary urinary infection of the kidneys. As yet, we do not know any way of clinically differentiating these two groups of cases.

I do not believe that I disagree with Dr Aub in anything except that I thought that a tumor would be found. We both agree that the patient should have been operated on.

DR OLIVER COPE: In all these cases the surgeon has to have a certain sort of conviction that the patient has hyperparathyroidism, because if he is not convinced beforehand he may not go the whole length, and as you know, it is not always easy to uncover all four parathyroid glands. Obviously, uncovering three glands may not be enough under such circumstances, if the three uncovered turn out to be normal. If four glands are found with no gross evidence of disease, he must wonder if he has not overlooked a fifth, because a certain number of people have five glands. I emphasize this because the hunt often takes a long time. In other words, I believe the surgeon must be convinced that the diagnosis is correct.

I agreed with Dr Albright, as opposed to Dr Aub, that there was a good likelihood that this patient had hyperparathyroidism. So I was willing to take the time to look. The reason I say that is that I do not believe that Dr Albright has enlarged enough on some of the experiences that we have had in operating on these patients. Only a year ago we operated on just such a patient. I went away from the table very discouraged, having uncovered four parathyroid glands that, so far as I could tell, were grossly normal. I took out the largest of the four because it was a little more globular in form than the other three, and to my great delight Dr Castleman found a tiny, minute adenoma in it, and the subsequent changes of metabolism confirmed Dr Castleman's anatomic diagnosis. In other words, what one must look for is not a big adenoma but rather something about the size of the head of a black-headed pin. To go back to the x-ray findings, I paid little heed to the report of the x-ray taken after the barium swallow. If there is displacement of the esophagus or the trachea or if there is a palpable nodule in the neck, it is a thyroid, not a parathyroid, tumor. Actually I could not find anything in this case to account for the x-ray findings.

At operation we uncovered four glands. They had a disturbingly normal color. The first one, the left lower, was a little larger than the average gland but the color appeared normal, that is, the relative distribution of fat cells to epithelial parathyroid cells seemed to be within the limits of normal. That was discouraging because, if there is a hyperactive adenoma in one, the other glands ought to be atrophic. This gland did not appear to be atrophic. The upper one on the left and the two on the opposite side were then uncovered, and all were within the normal limits. I took out a portion,

about 80 per cent, of the lower one on the right because it was pear shaped, and I wanted to be sure that it did not contain a minute adenoma. I left the top of it, being quite sure that there was no adenoma in this remnant. About 20 per cent of each of the other three glands was resected, to see if Dr. Castleman could find any evidence of secondary hyperplasia.

CLINICAL DIAGNOSES

Parathyroid adenoma

Nephrolithiasis

DR. AUB'S DIAGNOSIS

Renal stones due to pyelonephritis and secondary renal calcification

ANATOMICAL DIAGNOSES

(Nephrolithiasis)

Normal parathyroid glands

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN: We sectioned all four glands and found them to be normal. In each, more than half the gland was composed of fat cells and the epithelial cells seemed to be normal in size. If this had been secondary hyperplasia or an adenoma, the fat cells would have been replaced in the case of hyperplasia by an increase in the number of cells and in the case of adenoma by an increase both in the number and in the size of the cells, in other words, hyperplasia and hypertrophy. There was no suggestion of any degree of hyperplasia or hypertrophy.

DR. AUB: Feeling much more confident, I should like to add that this work of Randall's is extremely interesting. The condition that he has described occurs in youth as well as in later life. The papillae of the kidneys develop small areas of calcification below the mucous membrane, which eventually ruptures. With the passage of urine over this denuded calcification the stage is set for the accumulation of a stone of any kind. This must be a source of a fair number of stones.

DR. CASTLEMAN: Has there been any change in the patient's condition since operation?

DR. COPE: The patient was given penicillin before and after operation to decrease the urinary infection, and he told me that after that for the first time in several years he was free of discomfort in the back bilaterally, suggesting that the infection had diminished. That is the only thing that he noticed clinically.

DR. ALBRIGHT: A culture of the urine gave no growth.

CASE 32022

PRESENTATION OF CASE

A fifty-one-year-old electrician entered the hospital complaining of chills and fever.

Eighteen months before admission, the patient drank some pasteurized but apparently spoiled milk.

A short time later he noticed chills, fever and sweating. These symptoms occurred daily and seemed worse in the middle of the day. There were occasional afebrile days, but they became less frequent. During the next two months he lost 10 pounds and became extremely weak, with a sensation of fullness in the left upper quadrant of the abdomen. He was bedridden for ten weeks. A blood culture was said to be "positive" for *Brucella abortus*. A blood transfusion resulted in marked improvement. He returned to work and felt well during the next seven months. At the end of that time he noticed enlargement of the cervical lymph nodes. He again complained of chills and fever and was hospitalized. He received a transfusion from a patient who had recovered from undulant fever and showed great improvement. Two months later he again became ill and entered a local hospital. At that time an eruption of red spots that lasted a day appeared over the entire body. A blood transfusion again improved his condition, but two months later his symptoms recurred. One month before admission he entered another hospital with chills, fever, sweating and a sensation of fullness in the left upper quadrant. At that time transfusions resulted in no improvement. He was treated with sulfadiazine. Anemia and leukopenia, which had been present since the onset of the illness, persisted. Blood cultures and agglutination tests were negative for *Br. abortus*. The blood was negative for malarial parasites.

The past history was negative.

Physical examination showed a poorly nourished, pale patient who was perspiring profusely. The mucous membranes were pale, and the tongue was smooth. Numerous fused, firm, nontender, immovable nodes were palpable on the right side of the neck, and many small, firm, discrete nodes were present in the left cervical region. The heart and lungs were normal. The spleen was firm and extended to the level of the umbilicus. The liver was percussed one fingerbreadth below the right costal margin on deep inspiration.

The temperature was 97.6°F, the pulse 80, and the respirations 20. The blood pressure was 110 systolic, 80 diastolic.

The red-cell count was 3,360,000, with 10.5 gm of hemoglobin. The white-cell count was 2600, with 63 per cent neutrophils and 28 lymphocytes. Platelets were seen in normal numbers. The urine was red and acid and had a specific gravity of 1.022. It gave a + test for albumin, and the sediment contained hyaline casts as well as 2 to 5 white cells and an occasional red cell per high-power field. The nonprotein nitrogen was 25 mg per 100 cc, and the total serum protein 4.1 gm, with 2.8 gm of albumin and 1.3 gm of globulin. The serum chloride was 97 milliequiv per liter. Tests for agglutinins against typhoid and brucellar organisms were negative. A culture of the urine showed a moderate number of

colonies of *Staphylococcus aureus* and rare diphtheroid colonies. Stool culture was negative for pathogens.

An x-ray film of the chest showed large clear lung fields. The diaphragm was somewhat low in position. The heart and upper mediastinum were not remarkable.

A lymph-node biopsy was performed.

DIFFERENTIAL DIAGNOSIS

DR LOWREY DAVENPORT We have a man of fifty-one years whose essential symptom during the period of eighteen months was recurrent fever and whose significant positive findings on physical examination were enlargement of the cervical lymph nodes, enlargement of the spleen and moderate enlargement of the liver.

In the differential diagnosis we have to consider all the possibilities that would cause a relapsing fever over a period of eighteen months, considering separately, if you will, all the possibilities causing cervical adenopathy and enlargement of the spleen, to see if we can tie in the physical findings and the symptomatology. We are faced at the onset with the gratuitous finding given in the early part of the history of a positive culture for *Br abortus*. Subsequent cultures, however, were negative, as were agglutination tests for typhoid fever and brucellosis. We have to decide what we are going to do about this one positive culture. It seems unlikely in a case that has been observed for a period of eighteen months with repeated subsequent negative cultures and agglutination tests that the finding of a single positive culture for *Br abortus* should be accepted. We are told that the patient did drink spoiled milk, but we are also told that it was pasteurized, and it is inconceivable that *Br abortus* could have been present in the milk after pasteurization. Furthermore, his clinical record over a period of eighteen months is decidedly against undulant fever: he developed a rather marked anemia, a cervical adenitis and an enlarged firm spleen, all of which are unusual in brucellosis. The course of undulant fever over a period of eighteen months should have given a better clue to the diagnosis, and in spite of the history of his having drunk spoiled milk and the one positive culture, I shall throw out that diagnosis.

In considering fevers of unknown origin lasting for this period of time, we have the more frequent types, such as hidden tuberculosis or a hidden focus of pyogenic infection, and several obscure types. Recurrent malaria appears to have been ruled out by negative smears. I believe that recurrent rheumatic fever can also be ruled out: the patient was carefully observed for eighteen months without evidence of joint involvement. When one is faced with a situation of this sort, with a hidden focus of infection, the liver is usually the cause of the prolonged fever. We are all aware that the ordinary types of pyogenic infection of long duration show

intermittent leukocytosis, and certainly after one and a half years they should give definite information concerning the site and location of the focus of sepsis. We can rule out pulmonary tuberculosis since the patient had a completely clear x-ray film, at admission, but lymph-node tuberculosis must be considered in a separate category.

In a long continued fever of this sort, with progressive anemia, we have to think of the possibility of subacute bacterial endocarditis. There was no evidence, however, of peripheral emboli, also, the blood showed a marked leukopenia rather than a leukocytosis. Furthermore, the heart was normal on physical examination. Thus, at least three of the several criteria for making the diagnosis of subacute bacterial endocarditis are lacking.

There are several rare types of prolonged fever that should be mentioned in passing. Almost by the definition of his symptoms, this man had relapsing fever. Could this have been the type of relapsing fever that is due to spirochetal organisms? I think that we can exclude this diagnosis on several grounds. It has been reported, either louse borne or tick borne, in North America, but it is an exceedingly rare condition in this part of the world. Also, it is usually, in fact almost invariably, associated with leukocytosis, and we should not expect to have the finding of enlarged cervical nodes or an enlarged spleen. So most of the common infectious types of fever can be thrown out of the picture.

We should now consider the finding of large nontender immovable cervical nodes, with an enlarged spleen, which was firm, and a moderately enlarged liver. In considering a diagnosis that ties up the enlarged cervical nodes and the enlarged spleen, two things immediately come to mind. The first and likeliest possibility on that basis is Hodgkin's disease. We are all familiar with the particular form of Hodgkin's disease that goes under the name of "Pel-Ebstein type," which is characterized by recurrent episodes of septic temperature over a period of months or years, there are lymph-node enlargement and progressive anemia, and the disease finally leads to death. This is an intriguing possibility and should be seriously considered in arriving at a presumptive diagnosis. Since we are faced with confusing laboratory data and a confusing clinical picture for one and a half years, we must take it for granted that the diagnosis that we shall make before hearing the report of the biopsy is bound to be presumptive. What is against a diagnosis of Hodgkin's disease? This man, who had been hospitalized several times in a year and a half, with repeated blood examinations, had never shown any of the characteristic changes of Hodgkin's disease in the blood picture. Although the blood findings in Hodgkin's disease are never pathognomonic, a relative leukocytosis is sometimes observed during the course of the disease and an eosinophilia is often present. We have no record here of an early

blood examination, but the meager findings we do have regarding the later blood picture seem to cast some doubt on this being the usual type of Hodgkin's lymphoma

Could these have been tuberculous cervical lymph nodes? It is possible for such nodes to cause long continued intermittent fever, although such a condition now is rare, owing to the widespread pasteurization of milk. A septic type of fever, however, accompanied by profuse sweating, and other evidence of sepsis, as described in this individual, are rare unless the nodes are involved by secondary infection. We are told that the nodes were nontender and that they showed no evidence of suppuration. So we can assume that a noncomplicated tuberculous adenitis did not cause this picture.

What other forms of blood dyscrasia can cause enlarged cervical nodes and a large spleen? This man was repeatedly observed, but apparently showed no evidence of leukemia in the peripheral blood. One must always consider the possibility of leukemia in an aleukemic phase, better termed a "sub-leukemic" phase, since the leukemic elements are present if searched for. It seems likely that sometime during the course of eighteen months the typical picture of leukemia in the peripheral blood would have been found, so that the blood dyscrasias, particularly one of the leukemias, can be discarded.

We are faced with another intriguing possibility in a patient of this sort, that is, the disseminated form of lupus erythematosus. It is a condition that has come to be recognized more and more as an entity that should be considered in the differential diagnosis of long continued obscure fevers and obscure conditions with protean manifestations. Undoubtedly, the butterfly distribution of the erythema and the erythema itself have been greatly overemphasized. We now recognize that it is possible to have hidden forms of disseminated lupus without the typical erythematous eruption and the butterfly distribution. Lupus erythematosus can cause enlargement of the cervical nodes and an enlarged spleen. Over a period of eighteen months it can produce a recurrent intermittent type of fever and a progressive anemia, and also a change in the blood picture, which in the late stages is almost invariably a leukopenia. There are other things in the history that should make us consider this diagnosis carefully. There is no report of the chronic skin change that frequently accompanies the disease, but on one hospital admission the patient had a transient erythematous rash. In the late stages of disseminated lupus, because it is a disease of protean manifestations with generalized disorder of various organs in the body, one quite frequently obtains evidence of involvement of the kidneys, such as red cells, albumin and casts, which were found in this man's urine.

How much emphasis should we lay on the reports of the urine cultures? If this man had had a focus

of infection in the kidneys sufficient to give this type of clinical course over one and a half years, I should think that the early symptoms would have been more prominent than those given in the history.

We are thus finally faced with two possibilities—Hodgkin's disease, with the Pel-Ebstein type of temperature, and the disseminated form of lupus erythematosus. We must now decide which better fits the picture. One thing is definitely against disseminated lupus. It is a disease with a predilection for young women, in certain series the incidence having been as high as 90 per cent. That does not militate completely against the diagnosis, however, because the disease has been reported in men as old as seventy. Although the chances are against lupus because of its usual sex distribution, it must be seriously considered because of the clinical course. There are two or three things against Hodgkin's disease. In the first place, the cervical nodes are described as being fixed, whereas the nodes in Hodgkin's disease, as differentiated from tuberculous nodes, are usually said to be freely movable. Also, as previously mentioned, there is no indication that during the course of eighteen months he had any of the specific changes in the blood picture that frequently accompany Hodgkin's lymphoma. The age and sex distribution, however, favor this diagnosis. It is of common occurrence in men in the third and fourth decades, whereas disseminated lupus usually occurs in the second and third decades in women. Realizing that any diagnosis is only presumptive and that a positive diagnosis can be given only by the microscopical findings, I shall put down my first choice as disseminated lupus, with Hodgkin's disease second.

DR WYMAN RICHARDSON. This patient came in while I was on service. One interesting feature was that the temperature chart showed a double peak. I do not know what that means. I might add that the description of the nodes in the record is inaccurate, they formed a real mass, which I do not believe one sees in disseminated lupus. In the cases that I have seen the enlargement has been more diffuse and not so localized. I should think that that was against disseminated lupus. I also considered the possibility of sarcoid, but I had never seen such a severe case with as high a fever. I, too, considered malaria, but the smears were negative. So I came down to a diagnosis of Hodgkin's disease, with a possibility of sarcoid.

So far as the blood picture of Hodgkin's is concerned I do not believe that one can lean on it from the negative point of view, sometimes there are suggestive features from a positive point of view. The other point I should like to make is that most patients with a big spleen have a leukopenia whatever the cause, excluding, of course, true leukemia, polycythemia and infarction of the spleen.

CLINICAL DIAGNOSIS

Hodgkin's disease?
Sarcoid?

DR DAVENPORT'S DIAGNOSIS

Disseminated lupus erythematosus?
Hodgkin's disease?

ANATOMICAL DIAGNOSIS

Malignant lymphoma, Hodgkin's sarcoma type,
involving cervical and retroperitoneal lymph
nodes, spleen and bone marrow

PATHOLOGICAL DISCUSSION

DR. BENJAMIN CASTLEMAN The biopsy showed Hodgkin's disease of the sarcoma type, a very malignant form, with many Sternberg-Reed cells. The patient received x-ray treatment but died a few weeks later. At autopsy the spleen was tremendous in size, weighing over 1100 gm, and was infiltrated with yellowish nodules. Microscopically it was replaced with Hodgkin's sarcoma. There is a difference of opinion whether Hodgkin's disease is a granuloma or a neoplasm. In this laboratory we believe that it is a neoplasm rather than a granuloma, and a case like this seems to confirm our belief.

The finding of *Br abortus* in a case of Hodgkin's disease brings up the recent work of Forbus and his colleagues*. They were able to find *Brucella* in a large percentage of cases of Hodgkin's disease.

*Forbus W D et al. Studies on Hodgkin's disease and its relation to infection by *Brucella*. *Am J Path* 18:745-748 1942

They also injected the organisms into animals and produced a picture somewhat similar to, but certainly not characteristic of, Hodgkin's disease. This work has not been confirmed, and I believe that most pathologists are skeptical of this connection.

The abdominal and cervical nodes and the bone marrow were diffusely involved. The bone-marrow involvement might have accounted for the anemia.

DR. RICHARDSON It was not the blood picture of myelophthisic anemia.

DR. CASTLEMAN Nevertheless, the vertebral marrow was almost completely replaced by sarcoma.

DR. CHESTER M. JONES I should like to comment on the question of brucellosis. I saw a good many of Forbus's cases and talked with the group at Duke University only a few weeks ago. I think that they are in general agreement now that brucellosis has nothing to do with Hodgkin's disease. In the neighborhood of Durham brucellosis is endemic and a good many people in the community have it. Its presence in Hodgkin's disease was simply an incidental finding.

DR. CASTLEMAN Most people have thought that right along.

DR. J. H. MEANS Do we see Hodgkin's disease with tuberculosis any more?

DR. RICHARDSON We do not see it nearly so much as formerly.

DR. CASTLEMAN In the last ten or fifteen years we have seen only two or three cases of Hodgkin's disease associated with tuberculosis.

NEW YORK CITY RESTRICTS THE SALE OF PENICILLIN

WHenever a new agent becomes available and is proved useful in the treatment of disease, a problem arises concerning the extent to which its sale and distribution should be controlled. In general, federal and local authorities have been loath to apply restrictions, and when they have made attempts to do so, they have not always succeeded in withstanding the pressure from pharmaceutical and other manufacturers who are anxious to profit from the new developments. Unfortunately, many manufacturers are always ready to cash in on any wave of popularity and are not always interested in whether or not the best public good is served by

the widespread use of the product from which they derive their profits. On the other hand, the more reputable pharmaceutical firms have learned that in the long run their own best interests coincide with those of the public welfare and are best served by the carefully controlled production and distribution of products the value of which is thoroughly proved.

There are now available federal laws and regulations governing the sale and distribution of many medicinal products. In general, the purpose of these laws is to prevent the sales in interstate commerce of new substances that may be harmful and to permit the sale of such medicinal agents only after they have been proved to be of value. The Food and Drug Administration has also attempted to control advertising and labeling so as to prevent the making of unwarranted claims, while at the same time permitting the dissemination of information concerning the proper uses of new remedies.

Since most of the known drugs and biologic agents that are therapeutically active may also produce harmful side-effects, the restrictions on the sales of such agents are readily justified. The sulfonamide drugs can readily be included in this class, and there is little doubt that serious harm may result from their uncontrolled use. Regulations for bidding over-the-counter sales of sulfonamides are readily justified on this score. The demonstration of serious sensitization from the use of these agents in ointments, bandages, cosmetics, shaving creams and similar products is sufficient reason for restricting their sales in this manner. The physician who prescribes these products implicitly assumes the responsibility for seeing that they are used in a manner that minimizes their dangerous side-effects.

In the case of penicillin, toxic reactions, although by no means absent, are relatively infrequent and usually not severe. Many manufacturers are undoubtedly most anxious to have the opportunity of including the word "penicillin" on the labels of their products and to use this as a selling point, irrespective of the amount, activity or usefulness of the material that is incorporated. Great pressure will probably be brought to bear, as soon as the antibiotic is produced at a sufficiently low cost, to obtain permission to include penicillin in oint-

ments, bandages, eye lotions, shaving creams and many other products in which the particular manufacturers are interested. That such practices are not in the public interest is readily apparent to physicians, but it remains to be seen whether it is possible legally to prevent them. The facts that the manufacture of penicillin is largely in the hands of large and reputable manufacturers and that each batch must be carefully tested and approved by the Food and Drug Administration, may serve as a deterrent. Unscrupulous manufacturers, however, are not likely to submit to such rigid control, since the increased cost would make their ventures less profitable.

The Department of Health of the City of New York* has recently added a section to its Sanitary Code that re-

stricts the sale of preparations containing penicillin or other antibiotic drugs to persons presenting a written prescription of a physician, dentist, podiatrist or veterinarian, except in the case of preparations that the Department of Health may specifically exempt from the provisions of that section. This action was based on the fact that indiscriminate use of penicillin and other antibiotics may be dangerous. One of the hazards listed is that undertreatment in many diseases may alleviate the symptoms of illness without curing the disease, which, in turn, may continue to produce damage in the patient and to be communicable to other persons. Other reasons given were that "there is accumulating evidence of the possible importance of the development of penicillin-fast strains in persons who are inadequately treated" and that "antibiotic drugs have been so recently developed that there has not been sufficient time to determine the possible toxic reactions." Whenever evidence

is presented to the Department of Health that a certain preparation containing an antibiotic is entirely harmless yet effective in the treatment of disease, the matter of exemptions is duly considered. Under this provision an exception has already been made that permits the over-the-counter sale of bandages that contain a specified concentration of tyrothricin for external application to the human skin.

The action of the health authorities of New York City is certainly a step in the right direction. The principles on which this step was based are particularly commendable. It is doubtful that many other local authorities would have been willing to apply those principles to the dispensing of penicillin, on the other hand it is hoped that this regulation will lead to similar steps elsewhere.

MASSACHUSETTS MEDICAL SOCIETY POSTWAR LOAN FUND

The Postwar Loan Fund has been set up, and all discharged medical officers who were members of the Massachusetts Medical Society in good standing at the time of their entry into the service may apply for loans from this fund. For further information apply to.

ROUTINE BLOOD TESTS FOR SYPHILIS

THE value of routine blood tests for syphilis in large groups of people has been demonstrated again and again as an essential item in control of the disease. If further evidence is needed, a recent analysis of 5000 inductees in whom positive serologic tests for or a definite history of syphilis were found is convincing †

In nearly 60 per cent of the group syphilis had not been recognized and consequently had not been previously treated. At the same time it is pointed out that more evidence than a single positive serologic test is necessary to establish a diagnosis of syphilis. Thus, in 11 per cent of the cases no diagnosis of syphilis could be made after a careful history, detailed physical examination, spinal-fluid examination and further blood examinations. In another 11 per cent the syphilis had apparently

*Sale of antibiotic drugs restricted. *Quart. Bull. Dept. of Health, City of New York* 13:33 1945

†Zellermayer, J. Syphilis in inductees: analysis of 5000 cases. *J. Fen. Dis. Inform.* 25:194-198, 1945

been adequately treated, since no evidence of the disease was found. In 13 per cent, the disease had progressed to a point where cerebrospinal, cardiovascular or other complications were demonstrable. In the remainder (65 per cent) the disease had been inadequately treated or untreated, and although evidence of disease still persisted, there were no complications. The last group contained a few cases of primary and secondary syphilis, but the bulk of them were early latent cases, with a few late latent cases, in other words, the disease was recognized before any of the serious organic changes had appeared.

The report emphasizes the need of careful diagnostic work to avoid the treatment of nonsyphilitic persons. The positive serologic test is a pointer toward the diagnosis of syphilis, but too much reliance should not be placed on the result of a single test and the patient's history should be obtained and his examination should be conducted with proper care.

MASSACHUSETTS MEDICAL SOCIETY

BLUE TRIANGLE EXPANDS

Since the inauguration of the Blue Triangle late in 1944 much progress has resulted in making this plan available on both a statewide and a nationwide basis. The Massachusetts Medical Society, the Massachusetts Dental Society and the Massachusetts Bankers Association have co-operatively produced and promoted the Blue Triangle to the extent that this service is now available in forty-five Massachusetts banks. In one bank alone it is reported that more than sixty of their local physicians and dentists are now using this modern method to assist their patients in paying for essential medical and dental care.

Inquiries about the Blue Triangle have been received from various sources in forty-five of the forty-eight states. This is most encouraging, for once again Massachusetts has led the way with a splendid example of co-operation directed to the public welfare.

The medical profession has already developed the Blue Cross—a prepayment plan for hospitalization—and the Blue Shield—a prepayment plan for medical care. Both plans are like insurance—fine if there is a loss and if the particular loss is fully covered. But certain people are not so insured,

or their particular expenses are not covered. The Blue Triangle fills this need.

For the benefit of those doctors who have just returned from the service and may not be acquainted with the Blue Triangle, and for those who may have overlooked investigating its possibilities, the following is a brief outline of how the plan operates. When the patient contracts for or has accrued a bill larger than he can ordinarily pay out of a week's or month's wages, he is asked by the physician if he would prefer to pay the sum due in regular installments over a six-month to twelve-month period at the local bank that is participating in the plan. If the patient agrees, he signs a note, which the doctor transfers to the bank. The patient then repays the bank in monthly installments. In this way the doctor receives his money from the bank at the time he sends them the note, less a reserve (ordinarily 10 per cent). This reserve is paid to the doctor on final payment of the note by the patient. In this way the patient obtains a loan when he needs it with a minimum of effort and at a rate lower than he could obtain on a regular personal loan.

The Blue Triangle, although it has made great strides in the past year, is expected to be of even greater service in the years to come. With so many men and women coming out of the service who will again be calling on the family doctor, the Blue Triangle is bound to be of use to them when unexpected medical expenses arise. This is especially true when people are able to buy automobiles, appliances and the many other things they are waiting for. Furthermore, returning doctors who are re-establishing their practices will find it helpful from a financial standpoint.

The Blue Triangle is truly a health-financing service. Additional information regarding the plan may be obtained from the Massachusetts Medical Society.

DEATHS

DAVENPORT—Benita C Davenport, M D, of Middleton, died December 20. She was in her fifty-eighth year.

Dr Davenport received her degree from the Boston University School of Medicine in 1930. She became assistant physician at Essex Sanatorium in 1933 and served as senior physician from 1937 until ill health forced her to retire in 1943. She was a fellow of the American Medical Association and a member of the American Tuberculosis Association, the American Sanatorium Association and the American Trudeau Society.

Two sisters survive.

DRUMMEY—Nicholas D Drummey, M D, of Dorchester, died December 18. He was in his eighty-first year.

Dr Drummey received his degree from Harvard Medical School in 1887. He was the oldest alumnus of the Carney Hospital and was a consultant on the staff of the Faulkner Hospital. He was a fellow of the American Medical Association.

A son survives.

Undulant fever	5	4	5
Whooping cough	659	498	557

*Made reportable December 1943

†Four-year average.

COMMENT

Cases of lobar pneumonia were reported less frequently during November, October and September than at any time during these same months since 1918, they were about one third the seven-year median

The number of cases of scarlet fever during November was substantially below the seven-year median and approximately 30 per cent less than that during November, 1944

Whooping cough remains higher this year than for comparable periods last year

Cases of anterior poliomyelitis dropped from 136 in October to 50 in November The latter figure, however, represents the highest number of cases for November since 1935, when 58 cases were reported

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Becket, 1, Boston, 7, Brockton, 1, Brookline, 1, Chelsea, 1, Chicopee, 1, Everett, 1, Fitchburg, 5, Groton, 1, Haverhill, 1, Lowell, 1, Lynn, 2, Malden, 2, Marlboro 1, Medford, 1, Orleans, 1, Palmer, 1, Pepperell, 1, Pittsfield, 1, Princeton, 1, Quincy, 3, Reading, 2, Saugus, 1, Somerville, 1, Walpole, 2, Wareham, 2, Watertown, 1, Weymouth, 4, Worcester, 2, total, 50

Diphtheria was reported from Adams, 1, Boston 6, Gloucester, 4, Lowell, 1, Malden, 1, Melrose, 1, New Bedford, 1, Somerville, 2, Winthrop, 1, total, 18

Dysentery, amebic, was reported from Boston, 1, total, 1

Dysentery, bacillary, was reported from Boston, 2, Braintree, 1, Cambridge, 2, Camp Edwards, 1, Lowell, 2, Malden, 1, total, 9

Encephalitis, infectious, was reported from Lawrence, 1, Worcester, 1, total, 2

Lymphocytic choriomeningitis was reported from Quincy, 1, total, 1

Malaria was reported from Boston, 8, Brookline, 1, Camp Edwards, 5, Cambridge, 2, Cushing General Hospital, 2, Dedham, 2, Everett, 2, Gloucester, 1, Lunenburg, 1, Lynn, 1, Fort Devens, 8, Milton, 1, Regional Hospital (Waltham), 5, Springfield, 1, Wakefield, 1, total, 41

Meningitis, meningococcal, was reported from Auburn, 1, Boston, 3, Fall River, 1, Framingham, 1, Marblehead, 1, North Adams, 1, Quincy, 1, Topsfield, 1, total, 10

Meningitis, Pfeiffer-bacillus, was reported from Cambridge, 1, Mansfield, 1, Randolph, 1, total, 3

Meningitis, pneumococcal, was reported from Brookline, 1, Natick, 1, Swampscott, 1, total, 3

Meningitis, other forms, was reported from Boston, 3, Milton, 1, total 4

Meningitis, undetermined, was reported from Haverhill, 1, Worcester, 1, total, 2

Salmonella infections were reported from Boston, 1, Billerica, 1, Brookline, 1, Lowell, 1, Malden, 2, Salem, 1, total, 7

Septic sore throat was reported from Boston, 1, Fall River, 1, Lynn, 1, Newbury, 1, Somerville, 1, total, 5

Tetanus was reported from Boston, 1, Framingham, 1, total, 2

Trichinosis was reported from Boston, 2, total, 2

Typhoid fever was reported from Boston, 1, Lawrence, 1, Waltham, 1, total, 3

Undulant fever was reported from Brookline, 1, Taunton, 2, Waltham, 1, Worcester, 1, total, 5

MISCELLANY

DR DENNY RETIRES

Dr Francis P Denny retired in November of this year as health officer of Brookline, after thirty-two years of unique service to that community Born in 1869, Dr Denny graduated from Harvard College in 1891 and from Harvard Medical School in 1895 He served an internship at the Massachusetts General Hospital, studied a year and a half in Berlin and Vienna and established himself in practice in Brookline in 1897

Among his contributions to public health were the establishment of a bacteriologic laboratory in Brookline in 1899, — the first in Massachusetts outside Boston, — the establishment of a tuberculosis pavilion as part of the Brookline Contagious Hospital in 1914 and the establishment of a dental dispensary in 1915 He inaugurated immunization against diphtheria in Brookline in 1923

For twenty-six years Dr Denny was responsible for the quarterly publication of the *Brookline Health Bulletin*, a sheet that is delivered to every household in the town, printing regularly the results of milk examinations, the rating of restaurants and much other timely health advice During his term of office Brookline was three times the winner of the health-conservation contest sponsored by the United States Chamber of Commerce

Dr Denny, in the course of a long and useful career, has been president of the Massachusetts Public Health Association, the Norfolk District Medical Society and the Brookline Anti-Tuberculosis Society and a member of the Executive Committee of the Massachusetts Tuberculosis League, now being its honorary vice-president

He has been succeeded as health officer by Dr Alfred L Frechette, a graduate of the University of Vermont Medical School in 1934 and of the Harvard School of Public Health in 1939 Dr Frechette was with the United States Public Health Service in North Africa in 1943 and 1944 and has been personal representative of Director Herbert H Lehman, of the United Nations Relief and Rehabilitation Administration, in Ethiopia He has been secretary of the New Hampshire State Board of Health for the past two years

LIST OF POTENTIALLY DANGEROUS
MATERIALS USED IN INDUSTRY

The following list of potentially dangerous materials used in industry has been recently prepared by the Division of Occupational Hygiene, Massachusetts Department of Labor and Industry The italicized items are trade names

MATERIAL	COMPOSITION
Acetylene tetrachloride	Tetrachlorethane
Agate	Chiefly free silica
Aqua ammonia	Ammonium hydroxide (ammonia water)
Aqua fortis	Nitric acid
Aqua regia	Nitric and hydrochloric acids
<i>Arcklor</i>	Chlorinated diphenyl
Banana oil	Amyl acetate
<i>Barco spot remover</i>	Benzol (25%) and carbon tetrachloride (75%)
<i>Breistol</i>	Petroleum naphtha
<i>Blacoval</i>	Trichlorethylene
<i>Carrene</i>	Methylene dichloride
Caustic soda	Sodium hydroxide
<i>Croclent</i>	Trichlorethylene
<i>Criste</i>	Diatomaceous earth (silica)
<i>Cresan</i>	Contains ethyl mercury phosphate
Chalcedony	Chiefly free silica
Chert	Chiefly free silica
<i>Cklorox</i>	Dichlorethyl ether
<i>Cklorox</i>	Sodium hypochloride

MATERIAL	COMPOSITION
Chrome green	Contains lead chromate
Chrome yellow	Lead chromate
Chrysotahale	Free silica
Circosol	Trichlorethylene
Coal gas	Carbon monoxide
Coal tar naphtha	Contains xylene
DDT	Dichlor diphenyl trichlorethane
Diatomaceous earth	Chiefly free silica
Ditto (duplicating ink)	Methyl alcohol (90%)
Dowcylene	Carbon tetrachloride
Dowicide	Chlorophenols
Dykanol	Chlorinated diphenyl
Fibrocel	Free silica and asbestos
Filter aid	Free silica
Flake caustic	Sodium hydroxide
Flint	Free silica
Freon 12	Dichlor difluoromethane
Fusel oil	Mostly amyl alcohols
Granite	Free silica (33%)
Gunk	Emulsifying agent in kerosene, with cresol (3-4%)
Halowax	Chlorinated naphthalene
Handyflux	Contains potassium fluoride
Hexone	Methyl isobutyl ketone
Kieselguhr	Chiefly free silica
Larses	Sodium fluorosilicate
Litharge	Lead oxide
Lye	Potassium or sodium hydroxide
Mersol	Denatured alcohol, ethyl acetate and gasoline
Methyl acetone	Methanol, methyl acetate and acetone
Muriatic acid	Hydrochloric acid
Nesol	Benzol (60%)
Oil of vitriol	Sulfuric acid
Pear oil	Amyl acetate
Perchloroethylene	Tetrachloroethylene
Per-cylene	Tetrachloroethylene
Permaclor	Trichlorethylene
Petrobenzol	Petroleum naphtha
Phillolo	Ether trichlorethylene or tetrachloroethylene
Prussic acid	Hydrogen cyanide
Pyranol	Contains chlorodiphenyl
Pyrene	Carbon tetrachloride
Quartz	Free silica
Quartzite	Free silica
Sand	Chiefly free silica
Santocel	Free silica
Silica gel	Free silica
Skellysola	Petroleum naphtha
Soda ash	Sodium carbonate
Solox	Denatured alcohol, ethyl acetate and aviation gasoline
Solbesso	Toluol, xylol and naphtha
Sonarol 5	Naphtha
Sonarol 73	Petroleum naphtha (41%), benzol (4%) and toluene (55%)
Sonarol 74	Petroleum naphtha (15%) and xylol (85%)
Stoddard solvent	High boiling naphtha
Sirippet (paint remover)	May or may not contain benzol
Synasol	Denatured alcohol (formula 1), ethyl acetate and aviation gasoline
Taxite (paint remover)	Benzol (30%)
Tollac	Benzol (50%)
Tolad	Trichlorethylene
Triasol	Trichlorethylene
Triclene	Trichlorethylene
Triclin	Trichlorethylene
Tripoli	Chiefly free silica
Troluol	Petroleum naphtha
Tromax	Trichlorethylene
V M and P naphtha	Petroleum naphtha
Varol	High boiling naphtha
Wood alcohol	Methanol

BOOKS RECEIVED

The receipt of the following books is acknowledged and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Trauma in Internal Diseases With consideration of experimental pathology and medicolegal aspects. By Rudolf A. Stern, M.D., assistant attending physician, City Hospital, New York City. With a foreword by Francis C. Wood, M.D., director of laboratories and of the Radiotherapy Department, St. Luke's Hospital, New York. 8° cloth, 575 pp. New York: Grune and Stratton, 1945. \$6.75.

The author has endeavored to present a series of critical case histories, especially those with exhaustive post-mortem findings, along with a description of experimental work, which has either confirmed or refuted the assumption of trauma as an etiologic factor for many internal diseases. In writing the text, the author has reviewed a great mass of literature represented in a bibliography of forty-three pages, which will be found at the end of the book. The material covers the whole range of internal diseases.

New Steps in Public Health Twenty-second annual conference of the Milbank Memorial Fund, April 12-13, 1944. 8°, paper, 148 pp., with figures and tables. New York: Milbank Memorial Fund, 1945.

This second volume of the 1944 conference is devoted to a discussion of chronic disease, medical care and the role of emotional and social factors in illness and to a number of articles on the public-health aspects of nutrition, written by various persons.

On Modern Syphilotherapy, with Particular Reference to Salvarsan. By Albert Neisser, M.D. Translated by Isabelle von Sazenhofen Wartenberg. With a biography and bibliography by Frances T. Gardner. 4°, cloth, 42 pp., with frontispiece. Baltimore: Johns Hopkins Press, 1945. \$1.00.

In this translation Miss Wartenberg has made available the paper of Dr. Neisser, first published in 1911. The text of the article is preceded by a short biography of the author, and appended to the text there is a complete bibliography of the writings of Dr. Neisser from 1874 to 1916. The volume is well bound and is a reprint from the *Bulletin of the History of Medicine*.

NOTICES

ANNOUNCEMENTS

Dr. James A. Halsted and Dr. Stanley Kimball announce the reopening of their offices with the Dedham Medical Associates at 743 High Street, Dedham. Dr. Curtis Prout will be associated with them.

Dr. Francis X. Walsh, having returned from active service with the United States Army, announces the reopening of his office at 632 Columbia Road, Dorchester.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

The regular meeting of the New England Society of Physical Medicine will be held at the Hotel Kenmore, Boston, on Wednesday, January 16, at 8 p.m. Dr. Arthur L. Watkins will speak on the subject "Studies in Electro-Diagnosis as Applied to Peripheral Nerve Injuries and Polyomyelitis."

A council meeting will be held at 6:00 p.m., followed by a dinner in the Empire Room at 6:30 p.m.

Members of the medical profession are cordially invited to attend the meeting.

PHI DELTA EPSILON SOCIETY

A meeting of the Phi Delta Epsilon Society will be held in the auditorium of Boston University School of Medicine, on Thursday, January 17, at 8:15 p.m. Dr. Samuel A. Levine will speak on the subject "Cardiac Murmurs."

Those interested are invited.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, JANUARY 17

FRIDAY JANUARY 18

- *9:00-10:00 a.m. Medical clinic. Isolation Amphitheater, Children's Hospital.
- *9:00-10:00 a.m. War and Nerves. Major Merrill Moore, U.S.A. Joseph H. Pratt Diagnostic Hospital.
- *10:00 a.m.-12:00 p.m. Medical staff rounds. Peter Bent Brigham Hospital.
- 10:50 a.m. Industrial Dermatoses. Dr. John G. Downing. (Post graduate clinic in dermatology and syphilology) Amphitheater, Dowling Building. Boston City Hospital.

MONDAY JANUARY 21

- *12:00 m.-1:00 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.

TUESDAY JANUARY 22

- *9:00-10:00 a.m. Medical clinic. Infants Hospital.
- *12:15-1:15 p.m. Clinicorontogenological conference. Peter Bent Brigham Hospital.

WEDNESDAY JANUARY 23

- *9:00-10:00 a.m. Surgical Aspects of Gastric and Duodenal Ulcer. Dr. Edward A. Cooney. Joseph H. Pratt Diagnostic Hospital.
- *12:00 m. Clinicopathological conference. Children's Hospital.
- *7:15 p.m. Graduate seminar in pediatrics. Children's Medical Service, Amphitheater 3A. Massachusetts General Hospital.

*Open to the medical profession.

Number 3

PROGRESS IN THE TREATMENT OF SUBACUTE BACTERIAL ENDOCARDITIS*

CUTTING B FAVOUR, M D,† CHARLES A JANEWAY, M D,‡ JOHN G GIBSON, II, M D,§
AND SAMUEL A LEVINE, M D||

BOSTON

IT IS extremely gratifying for the medical profession to witness progress in therapy, especially when it applies to ailments that were formerly fatal. To the diseases of this kind, such as diabetes, pernicious anemia, Addison's disease and various forms of bacterial meningitis, which in the past almost always resulted in death it may soon be possible to add some types of bacterial endocarditis. Among the common diseases of the heart, none has been so resistant to treatment and so invariably fatal as subacute bacterial endocarditis. Although isolated cures occurred before the introduction of the sulfonamides, there is little evidence that any previous type of therapy materially influenced the outcome. The purpose of this paper is to summarize briefly the experience of the Peter Bent Brigham Hospital in the treatment of 347 cases of this disease during the years 1913 through 1944.

The thirty years covered by this study have been divided into three periods. During the first period, 1913-1937, termed "the pre-sulfonamide era," a great many therapeutic procedures were carried out. During the second period, 1937-1944, called "the sulfonamide era," various sulfonamides were employed¶, and during the last period, from January, 1944, to the present writing, termed "the penicillin era," penicillin has been used**. In the first period, 237 cases of subacute bacterial endocarditis were observed, during the second 90 cases, and during the third 20 cases.

PRE-SULFONAMIDE ERA

The extraordinary fact stands out that before the introduction of sulfonamide therapy there was not

¶In this period 5 patients with patent ductus arteriosus and bacterial endocarditis also received a sulfonamide but these were operated on and are therefore not included in this series.

**In this period, 1 patient with patent ductus arteriosus and bacterial endocarditis received penicillin, but was operated on and is not included in this series.

a single known recovery in this series. Of the 237 patients treated in this period, 218 died in the hospital or shortly after discharge, and the rest went home critically sick and were not heard from. Among other hospital patients a temporary cure or arrest may have occurred, since there were several cases of apparent recovery in patients with a mild-course who had some of the evidences of subacute bacterial endocarditis but failed to show a positive blood culture. These cases were not included in the study.

It is interesting and somewhat humiliating to recall the variety of bizarre and fanciful methods of treatment that were tried in pre-sulfonamide days. One patient was infected with ratbite fever (*Spirillum minus*), another was given malaria, and a third was treated with typhoid vaccine shortly after fever therapy was introduced in the treatment of general paresis. A fourth patient received intramuscular turpentine to produce a sterile abscess, a fifth received intravenous bacteriophage, and a sixth had a resection of the breast with searing of the pectoral muscle, which had been advised by Bier¹. Others were given antistreptococcus goat serum or various chemicals, such as neosalvarsan, Optochin, gentian violet and acriflavine. Finally, in 2 cases living beta-hemolytic streptococci in increasing doses were injected subcutaneously with the hope of altering the immune state of the host. In no case was the outcome altered.

SULFONAMIDE ERA

Of the 90 cases in the second period, 55 received adequate treatment with one or another of the sulfonamide drugs, and 35 either were not diagnosed soon enough or received inadequate chemotherapy. The patients who received a satisfactory course of a sulfonamide can be further subdivided into two groups. Thirty-nine received the drug alone, and 16 were given fever therapy in conjunction with it.

Among the 39 patients who received a sulfonamide without fever therapy, there were no recoveries. Courses of sulfanilamide, sulfapyridine, sulfathiazole and sulfadiazine, alone or in sequence, were

used In 2 of these cases continuous intravenous heparin was given in conjunction with oral sulfapyridine, and in 1 dicoumarin was given with sulfadiazine. Heparin therapy was discontinued because of its apparent ineffectiveness, its cost and the difficulty of administration, and finally because of a fatal cerebral hemorrhage, probably due to em-

with the sulfonamides was their combination with fever therapy. Although great interest in the use of artificially induced fever in the therapy of bacterial disease followed the meeting of the Fever Conference in 1935,⁴ the emphasis in treatment remained on the diseases in which the in vitro sensitivity of the infecting organism to elevated

TABLE 1 Summary of Data *

CASE No	AGE	SEX	PROBABLE DURATION OF INFECTION	DENTAL HISTORY	SPECIES INFECTING ORGANISM	PENICILLIN SENSITIVITY	APPROXIMATE TREATMENT	RESULT	FOLLOW-UP
						units/cc			
1	14	F	1 mo	Infected tooth†	<i>Str viridans</i>	—	Sulfapyridine, 1 gm every 4 hr for 11 days; sulfathiazole, 1 gm every 4 hr, with 11 infra-red treatments	Well	4 yr ¹
2	25	M	19 days		<i>Str viridans</i>	—	Sulfadiazine, 1 gm every 4 hr, with 15 typhoid chills	Well	2 yr
3	25	M	2 mo	Gum infection	<i>Str viridans</i>	—	Sulfathiazole, 1 gm every 4 hr; sulfadiazine, 1.5 gm every 4 hr, with 10 typhoid chills	Well	3 yr
4	30	F	3 mo		<i>Str viridans</i>	—	Sulfadiazine, 1 gm every 4 hr, with 9 typhoid chills	Well	2 yr
5	20	F	1 mo		<i>Staph albus</i>	0.600-0.015	Penicillin 100,000 units a day by constant intravenous drip for 10 days and 8300 units intramuscularly every 3 hr for 9 days; Sulfadiazine 1 gm twice daily, maintenance dose; Penicillin 300,000 units a day by constant intravenous drip for 11 days and 50,000 units every 2 hr intramuscularly for 10 days	Relapsed in 6 wk	
								Relapsed in 2 mo and died from an other cause 10 mo later	
6	52	F	3 mo		<i>Str viridans</i>	—	Sulfadiazine 1 gm every 4 hr with 5 typhoid chills; sulfadiazine, 1 gm every 4 hr and neoarsphenamine, 400 mg, with 7 typhoid chills; Penicillin 240,000 units a day by constant intravenous drip for 12 days	Well, subsequent heart failure	1 yr
7	38	M	10 wk		<i>Str viridans</i>	—	Penicillin 240,000 units a day intravenously for 9 days and 20,000 units intramuscularly every 2 hr for 3 days	Died with cardiac arrhythmia 2 mo after treatment	
8	16	F	7 mo	Teeth cleaned and filled	<i>Str viridans</i>	0.001	At another hospital the patient received a sulfonamide with typhoid chills and with malaria inocula; at this hospital she received 200,000 units of penicillin a day by constant intravenous drip for 20 days	Well	1 yr
9	17	F	2 mo	Tooth extractions	<i>Str viridans</i>	—	Penicillin 240,000 units a day by constant intravenous drip for 16 days	Well	1 yr
10	61	M	2 mo		<i>Str viridans</i>	0.080	Penicillin, 300,000 units a day by constant intravenous drip with sulfadiazine 1 gm every 4 hr for 13 days	Well, limited cardiac reserve	16 mo.
11	56	F	3 mo	Upper teeth pulled	<i>Str viridans</i>	0.080	Penicillin 300,000 units a day by constant intravenous drip with sulfadiazine 1 gm every 4 hr, for 22 days	Well further limitation in cardiac reserve.	16 mo.
12	45	M	3 mo	Severe dental abscess	<i>Str viridans</i>	0.035	Penicillin 300,000 units a day by constant intravenous drip for 22 days	Well	1 yr
13	27	F	2 mo	Tooth infection†	<i>Str viridans</i>	0.035-0.070	Penicillin 300,000 units a day by constant intravenous drip for 15 days; Penicillin 500,000 units a day by constant intravenous drip for 23 days; Penicillin 20,000 units intramuscularly every 2 hr with benzoic acid regimen for 30 days and 20,000 units intramuscularly every 3 hr with benzoic acid regimen for 30 days	Relapsed in 7 days; Relapsed in 2 wk.	9 mo

*All patients had rheumatic heart disease except the one in Case 5 who had a postoperative infection following ligation of a patent ductus arteriosus; the one in Case 14 who had a bicuspid aortic valve and a patent ductus arteriosus and the one in Case 17 who had arteriosclerotic heart disease.

bolism, that complicated therapy in one of the above patients, as well as in another reported case.² The small size of this group and the rigid criteria for case selection probably account for the deviation in recovery from the usual 6 per cent rate reported elsewhere for sulfonamides alone.³

The most illuminating feature of our experience

temperature made in vivo therapy rational.⁶ The most encouraging results were obtained in gonococcal and meningococcal infections.⁶ Although a few patients with bacterial endocarditis due to *Streptococcus viridans* showed temporary improvement following short courses of fever therapy,⁷⁻⁹ a cure was not brought about. The additional

finding that many strains of *Str viridans* recovered from the blood of patients with subacute bacterial endocarditis survived and grew in vitro at temperatures above those that the patient could tolerate^{7, 10} furthered the neglect of fever treatment for this disease until Bierman and Baehr¹¹ reported their successes in 1941. In this hospital the use of fever

artificially induced fever by means of infrared radiation. It may be significant that this and other successful fever therapy cases underwent many more fever treatments than were used in the earlier failures with fever therapy alone. The first cure led to the unsuccessful treatment of 6 other patients in a similar fashion, and subsequently to the treatment

bolism, that complicated therapy in one of the above patients, as well as in another reported case.² The small size of this group and the rigid criteria for case selection probably account for the deviation in recovery from the usual 6 per cent rate reported elsewhere for sulfonamides alone.³

The most illuminating feature of our experience

temperature made in vivo therapy rational.⁵ The most encouraging results were obtained in gonococcal and meningococcal infections.⁶ Although a few patients with bacterial endocarditis due to *Streptococcus viridans* showed temporary improvement following short courses of fever therapy,⁷⁻⁹ a cure was not brought about. The additional

20,000 units every three hours for fifteen days more. With this schedule the salt intake was restricted to less than 3 gm a day, fluids were restricted to less than 1500 cc a day, and 2.5 gm of benzoic acid in capsules was given three times a day with meals. During therapy the patient remained on the benzoic acid regimen.¹⁸ At autopsy a healing vegetation measuring 1 cm by 3 cm by 0.1 cm was found firmly attached to the closure line of an aortic cusp. It contained no bacteria on smear, culture or microscopic examination of sections. The cause of death was acute coronary occlusion, possibly due to temporary obstruction of the left coronary orifice by the curtainlike vegetation.

The sixth death (Case 5) occurred in May, 1945, following a massive hemorrhage from a bronchus. The endocarditis had developed as a postoperative complication of an unsuccessful ligation of a patent ductus arteriosus. This hemorrhage occurred seven months after the first course of penicillin and nine months after all evidence of infection had disappeared. Autopsy revealed the original patent ductus arteriosus opening into a large aneurysmal sac in the pulmonary artery and a silver clip eroding a small branch of the pulmonary artery and the adjacent bronchus. Apparently one of the clips used in the ligation had been engulfed by the subsequent aneurysm and had been carried by the blood stream to the lung. There was complete healing of the mediastinum and vascular walls.

Two of these deaths (Cases 5 and 17), were in cases of proved bacteriologic cure, and in 1 (Case 7) the patient may have been free of vegetations.

DENTAL ASPECTS

Although isolated cases of subacute bacterial endocarditis following tooth extractions have been known for some years, it is only recently that the great significance of this factor has been appreciated. That bacteremia follows tooth extractions in 70 per cent of cases,¹⁹ frequently follows minor dental manipulations and may occur after the simple act of chewing has been established.²⁰ In this series of 347 cases the perfunctory dental histories of the routine records have revealed an incidence of tooth extractions in 10 per cent of the cases and other dental manipulations in an additional 10 per cent within several weeks before the onset of bacterial endocarditis. During the past two years, in which there has been a deliberate inquiry about dental sepsis as a part of the patient's present illness, its real importance has been demonstrated (Table 1). Among earlier patients numerous other foci of infection and a variety of surgical procedures have similarly acted as the origin of this infection — namely, tonsillectomy, sequestrectomy, abdominal operations (appendectomy, colostomy, tubo-oophorectomy and so forth), prostatic massage and others. Nevertheless, dental sepsis is the most prominent

offender. The significance of this factor is emphasized by bacteriologic differentiation of the causative organisms. Most edentulous patients who develop bacterial endocarditis are infected with the enterococcus, the staphylococcus or even the gonococcus, whereas the overwhelming majority of patients who still have their teeth are infected with *Str. viridans*, which is so generally associated with dental sepsis and the bacteremia attending dental procedures. It is because of these findings in patients with subacute bacterial endocarditis who need dentistry that we have completed necessary dental extractions and manipulations while the patients have been receiving penicillin, and have continued therapy until gum healing is complete. When the teeth are so poor as to constitute a subsequent threat of reinfection of the heart valves, we have removed all of them before completing treatment.

STREPTOCOCCUS SKIN TESTS

A final point of interest is the skin reaction to intradermal injections of streptococcus nucleoprotein. It is known that 85 per cent of cases of rheumatic fever show a positive reaction to beta-hemolytic streptococcus skin tests.²¹ It is the finding of others^{22, 23} and it has been our experience²⁴ that cases of subacute bacterial endocarditis rarely show such positive skin reactions. Post-mortem evidence of concurrent active rheumatic carditis and subacute bacterial endocarditis is not necessarily a contradictory finding, for there is reason to believe that the rheumatic state can be activated by or follow and need not precede the bacterial endocarditis.²⁵

At present the streptococcus skin test is a useful empirical diagnostic tool. Seventy-four of 77 patients with undoubted bacterial endocarditis have had negative beta-hemolytic streptococcus skin tests, and all 77 have had negative alpha-hemolytic streptococcus skin tests.* Eleven patients who had negative skin tests during active bacteremia developed positive alpha-hemolytic and beta-hemolytic streptococcus skin tests, either during or shortly after penicillin therapy, and have so far maintained their positive reactions.

DISCUSSION

It is fair to point out that all but 1 of the deaths following penicillin therapy were due to causes beyond the control of this drug. The successes, although not so fraught with bizarre complications as were the fatal cases, nevertheless were gained despite chronicity of the disease and advanced age, great debility and poor cardiac reserve of the patients. One patient (Case 6) developed congestive heart failure and had a cerebral hemorrhage or embolus during an unsuccessful course of fever and sulfonamide therapy several months before penicillin

*Details of these data will be presented elsewhere in a subsequent publication.

given typhoid vaccine, sulfadiazine and neoarsphenamine simultaneously. No one of these last 3 patients was cured by such desperate measures, whereas 1 (Case 6) was subsequently readily cured with a short course of penicillin.

When fever was induced by infra-red radiation, the rectal temperature was kept at 105 to 106°F (40.6 to 41.1°C) for three to five hours for eight or more treatments on alternate days. For typhoid-vaccine fever, 25,000,000 typhoid-paratyphoid organisms were injected intravenously for the first dose, and the amount was doubled at intervals of two or three days. The purpose was to obtain a temperature of 104°F (40.0°C) for several hours. Ten or twelve such treatments were usually given. In some cases the amount of vaccine was increased or decreased because the response was insufficient or excessive. Of the 16 patients who had this combination of fever and sulfonamide therapy, there were cures in 4 (Cases 1, 2, 3 and 4)* — the first such cures ever obtained in this hospital. These recoveries with combined fever and sulfonamide therapy are in accord with the ratio 4/25 reported elsewhere for hyperthermia⁸ and that of 5/17 for typhoid-vaccine fever and sulfonamides.¹²

PENICILLIN ERA

Of the 20 cases treated in the third period, 17 (Table 1) received adequate courses of penicillin, 2 were diagnosed post mortem, and in 1 no treatment was given because the patient was in terminal uremia on admission and the limited drug supply at the time did not justify treatment of an apparently hopeless case. Penicillin was given for two to four weeks in a constant intravenous drip of 5 per cent dextrose at the rate of 240,000 to 500,000 units a day. At the time of this writing, six to eighteen months following treatment, 11 of the 17 adequately treated cases are cured or arrested and 1 patient (Case 5) has been cured but has died of another cause. Three of these 11 patients (Cases 5, 13 and 18) required more than one course of penicillin. In 2 of the 17 adequately treated cases (Cases 10 and 11), sulfadiazine was given with penicillin. In a word, in 11 of the 17 well authenticated cases of subacute bacterial endocarditis the patients have responded favorably to penicillin therapy and have remained well for six to eighteen months.

Each of the 6 patients who died after adequate penicillin therapy presented a complicated problem. One (Case 7) died of congestive heart failure two months after penicillin was stopped. In the interval between treatment and death, auricular fibrillation, sweating and a rapid heart rate were present. During this time the patient remained afebrile and the blood cultures were sterile. Unfortunately, the

cause of death is not known, for the patient died at home and no post-mortem examination was made.

The second patient (Case 14) died of general septicemia three weeks after penicillin treatment was stopped. Repeated blood cultures before treatment contained *Str. viridans*. When penicillin was begun this organism disappeared from the blood, and it was not recovered again during life or from the post-mortem heart's blood. After a week of penicillin, a gram-negative bacillus, *Alkaligenes faecalis*, appeared in the blood cultures and persisted until death, despite further penicillin and later sulfadiazine therapy. At autopsy, both *Str. viridans* and *Al. faecalis* were cultured from vegetations found on a bicuspid aortic valve and a patent ductus arteriosus.

The third patient (Case 16), with a short illness had a positive streptococcus skin test on admission that became negative before treatment and during active bacteremia. The only clinical response to penicillin given by constant intravenous drip was control of embolic phenomena and bacteremia. High fever and debility persisted. After penicillin was discontinued, the blood cultures remained negative until death three weeks later. In this interval dermatitis exfoliativa and acute yellow atrophy appeared. At autopsy healing vegetations were found that when crushed and cultured yielded the same type of streptococcus as that found in life. In retrospect this patient was probably inadequately treated. We have since found it necessary to raise the penicillin dose by steps to well over 1,000,000 units a day to control systemic symptoms of the septicemia. When even this dose is inadequate, the addition of the benzoic acid regimen gives blood levels equivalent to a daily dose of 6,000,000 to 10,000,000 units a day.

The fourth patient (Case 15) responded favorably to a two-week course of 300,000 units of penicillin a day by constant intravenous drip. He remained well until four months later, when a splenic infarct took place and a low-grade fever appeared. Death from a ruptured spleen occurred two weeks later during an interval in which repeated negative blood cultures delayed the reinstitution of penicillin therapy. At autopsy, healed and healing vegetations were found that contained *Str. faecalis* by smear and culture. The splenic infarct was sterile. The infecting organism was different from the one recovered during the first illness, and this fact invites speculation whether the patient died of a reinfection rather than of a recurrence. A ruptured spleen in subacute bacterial endocarditis is infrequent.¹⁴⁻¹⁶ This case will be reported in detail elsewhere.¹⁷

In the fifth case (Case 17), death occurred suddenly three weeks following thirty days of penicillin therapy — 20,000 units every two hours day and night intramuscularly for the first fifteen days and

*Another patient recovered with sulfadiazine and typhoid vaccine therapy but was not included because blood cultures were always negative although he showed many of the other clinical features of bacterial endocarditis.

in other patients when the pattern of their illness was favorable as judged by symptoms, temperature, a rise in hemoglobin, a fall in the sedimentation rate and clearing of the urine. The change of the streptococcus skin reaction to positive usually occurred before treatment was discontinued and was interpreted as a favorable sign. One patient (Case 13), however, relapsed after such a change, and 1 (Case 19) did not have a positive reaction until some weeks after treatment but nevertheless recovered. In this series recovery has followed two weeks of treatment in some cases, as in Case 6, and as long as two months of treatment in others, as in Case 13.

With special attention to the penicillin dosage in subacute bacterial endocarditis, it should be possible to raise the recovery ratio to an even higher figure than that of 11/17 in this study, especially when the disease is recognized early, the organism is found to be sensitive to a certain level of penicillin and the dosage is planned accordingly.

SUMMARY

Three hundred and forty-seven proved cases of subacute bacterial endocarditis treated at the Peter Bent Brigham Hospital from 1913 to 1945 have been studied. There were no known recoveries among 237 cases seen between 1913 and 1937, during which time a great variety of therapeutic procedures were employed.

Of the 90 cases observed from 1937 to 1943, 55 received adequate treatment with a sulfonamide. Sixteen of the latter patients were given simultaneous fever therapy. Of these, 1 treated by infrared radiation and 3 treated by typhoid vaccine recovered and have remained well for two to four years. None of the other sulfonamide-treated patients recovered.

Of 20 patients studied since January, 1944, 17 were given large doses of penicillin. In 11 cases the infection has been cured or arrested, and the patients are now alive. The follow-up periods vary between six and eighteen months. In two others the infection was bacteriologically arrested but death occurred some weeks later because of complications.

Congestive heart failure may follow recovery from the infection.

Dental sepsis, extraction of teeth and dental manipulations were found to be related to the onset of this disease in a surprisingly large number of cases. Infected teeth should be removed before treatment is completed, as a prophylaxis against subsequent reinfection of the heart valves.

A change in the sensitivity of the skin to streptococci was found to vary with the stage of illness. The reaction was almost invariably negative during the active stage of infection (74 of 77 cases) and became positive in the patients who recovered (11 cases).

Although penicillin appears to be a promising cure for subacute bacterial endocarditis, patients who recover from this disease are left with the same or further valvular deformities, which continue to predispose them to reinfection or to subsequent congestive heart failure.

The successful treatment of a patient with subacute bacterial endocarditis is an individual problem that requires careful attention to the details of therapy. Successful treatment depends on maintaining penicillin blood levels considerably in excess of the minimal inhibiting concentration of penicillin for the patient's organism.

Abstracts of the 4 cases successfully treated with sulfonamides and of 14 of the 20 cases treated with penicillin will appear in the reprints of this paper.

was administered. Although now ambulatory, she is on constant digitalis therapy and suffers primarily from moderate congestive failure. Another patient (Case 10) was in congestive failure when the diagnosis of bacterial endocarditis was first made. Since recovery he has had two bouts of mild congestive failure without evidence of infection. A third patient (Case 8) was of interest because she showed evidence of acute nephritis before treatment. The urine contained considerable albumin and many red cells, white cells and casts. There was marked anemia, with a red-cell count of 2,600,000. Despite the severity of the illness, the response to treatment was most satisfactory. A fourth patient (Case 15) did well up to his recurrence or reinfection four months later, although before treatment he had had a cerebral embolism with hemiplegia. Functional recovery of the affected side of the body was almost complete. One patient (Case 2) treated with sulfadiazine and fever and 6 patients (Cases 5, 9, 10, 14, 18 and 20) treated with penicillin had arterial emboli after therapy had been stopped, but despite these did well. The inference to be drawn is that sterile emboli may occur without preventing a favorable outcome. It is also important that the physician be not unduly disturbed at unexpected rises in temperature during the course of treatment, because these are often due to local phlebitis at the site of the constant intravenous injection. He should, however, be concerned by a continuous fever during therapy, because this usually means inadequate amounts or methods of giving penicillin — as in Case 16. Another point of considerable significance is the fact of recovery in several cases even though treatment was begun many months after the onset of the disease and in spite of the patients' advanced age. It is obvious that the outlook is better when the diagnosis is made promptly, but it is comforting to know that favorable results can be obtained in patients who have been neglected for six months or more, as in Cases 6 and 8.

Studies with the streptococcus skin tests were of special interest in the penicillin-treated patients. At the present time one may speculate that whatever the state of immunity or sensitivity of the host to streptococcal infections before the development of bacterial endocarditis, the bacteremia effectively desensitizes as well as immunizes the host during infection. The prompt control of septicemia and splenomegaly and the early appearance of a positive streptococcus skin reaction during or following penicillin therapy suggest that the principal effect of this drug is to localize the valvular infection. The finding of viable streptococci in the valves in fatal cases that had received relatively short courses of penicillin (Cases 14, 15 and 16) and not in a patient treated for one month (Case 17) suggests that at least two, often three or four and sometimes even eight weeks of penicillin — as in Case 13 —

are necessary before the vegetations heal completely. Recurrent sterile emboli appearing during and shortly after treatment give further support to this theory. In the fatal case with a curtainlike vegetation (Case 17) the patient might well have had a sterile embolus during convalescence had he not died of another condition.

The use of large doses of penicillin in the treatment of subacute bacterial endocarditis was introduced by Loewe.²⁶ The aim of therapy is the maintenance of a penicillin blood level considerably in excess of the minimal inhibiting concentration for the patient's organism for an extended period of time. A higher level maintained for a short time does not seem to be an effective alternative mode of treatment, Case 13 is an example. Two hundred thousand or 300,000 units a day given either by constant intravenous drip or by two-hourly intramuscular injections day and night may serve to maintain such a level in the blood stream most of the time,²⁷ and do so continuously when combined with the benzoic acid regimen.¹⁸ Patients with a free aortic regurgitation may require as much as 1,000,000 units a day to maintain equivalent blood levels. The patient in Case 19 was treated by the constant intravenous drip method and the one in Case 20 with the benzoic acid regimen and intramuscular injections every two hours. In the latter patient it was found to be practical to give up to 80,000 units in 2 cc of saline solution, and this was done without any more local discomfort than is experienced with the usual dose of 20,000 units in 4 cc of saline solution. Despite these doses, the blood levels did not exceed fivefold the minimal penicillin concentration that inhibited their respective organisms.

Because of the importance of individualizing the treatment of subacute bacterial endocarditis, whenever possible we have determined the penicillin sensitivity of the patient's organisms and gauged the necessary amount of therapy by the lowest penicillin blood levels attained in treatment. From the cases covered in this report it appears that a blood level that remains just above or often falls below the minimal inhibiting concentration for the bacteria does not control symptoms or temperature. A good working rule is to maintain a blood level five or more times the minimal effective level. Just how this is to be done varies with the patient. By the same token, no set rules for the duration of therapy can be stated. In Case 13 the patient relapsed twice, both times after apparently adequate therapy. When therapy was continued the third time until the sedimentation rate had fallen close to normal, she recovered. The patient in Case 18 relapsed but responded to retreatment which was continued until after the microscopic hematuria was controlled. The sedimentation rate was not normal but became stabilized at a somewhat elevated level. Penicillin was discontinued

Each of these valuable adjuncts, however, has been enthusiastically ushered in, only to be later ranked as falling far short of being the unmixed blessing it seemed at first. Certainly, few can deny that the efficient care of obstructed patients calls for nicety of judgment, assiduous and diligent attention and individualization hardly demanded by any other group. Such cases do not lend themselves to standardization by any known therapeutic scale. It is with this precept in mind, rather than varying formulas of duration of obstruction, objective findings of abdominal tenderness, rigidity and the like or white-cell counts, that one should attempt to treat these patients.

Any series of acute intestinal cases with an unusually low mortality of necessity demands an accounting of the methods of diagnosis employed. Little question of diagnostic accuracy is encountered in the patients receiving operations, the finding in whom of obliteration of a section of bowel lumen, with dilatation of the bowel above and its collapse below the point, eliminates argument concerning classification. Justifiable critical scrutiny, however, may be aimed at the cases not operated on. Only one of our patients with hernial obstructions was not operated on, the ultimate diagnosis being confirmed at autopsy. This method of confirmation was applied to a case of obstruction due to a metastatic malignancy and to another due to mesenteric vascular occlusion. With the exception of these

admission and after two or more irritating enemas, typical peristalsis and roentgenologic demonstration of distended bowel, with fluid levels and absence of colonic gas. Failure to demonstrate any one or more of these diagnostic points has excluded many cases from the series.

Paramount in the criteria for judging the method of handling these problems is an assessment of the general condition rather than the local disease. We fear, as do all surgeons, the progression of bowel changes from obstruction to strangulation and finally to loss of viability, but we also believe these to be relatively overemphasized. We are convinced that it is better to operate on many of these patients six, eight or ten hours later, when they can tolerate the procedure, than to perform a possibly simpler and easier operation at once when they are too ill to stand it. We believe that it is safer to consider every patient with intestinal obstruction as critically ill and as a truly poor-risk patient, one who is actually too ill to withstand the operation that he nonetheless may require. Therefore, we do not allow our natural fear of local bowel change to carry the same weight as concern for the patient's general condition. The former is more obvious, more easily demonstrated and more readily evaluated, but the latter constitutes the greater threat to life.

Our method of treating acute obstruction of the small bowel is to provide surgical correction of the

cases and of those due to adhesions, all our diagnoses were confirmed at operation. Concerning the cases due to adhesions, the presence of complete obstruction may be difficult to decide with certainty without operation, and many patients who were treated conservatively have been omitted from this survey because there was a lack of one or more absolute criteria for the conclusion that obstruction was complete. Of this group of patients, 22 satisfied our criteria by the demonstration of intermittent, cramping abdominal pain, repeated vomiting, failure to pass gas or feces by rectum prior to

condition when the patient has reached the peak of general systemic improvement. Of course, some of these patients seek hospital care quite early in their illness, often permitting immediate surgery, but their number in municipal institutions is notably small. Even this group, however, receives what might be called prophylactic treatment for shock, intubation, suction and blood or plasma before and during operation, despite their apparently satisfactory condition on admission. The other, much larger, group demands an exhaustive study to assess its ability to counter the shocking effect of the

vanced physiological age as compared with the chronological age and, possibly most important of all, the educational deficiencies that bring them to medical care late in the course of their diseases. When these handicaps are compounded with an illness that in the best of hands carries a formidable

this condition is still one of the most serious seen by the surgeon.

It appears from an analysis of such results as are reported that a rate of about 20 per cent is a reasonable goal at which to aim. To illustrate this consensus, the mortality rates from some leading clinics are presented in Table 1.

Richardson¹² indicts acute obstruction for causing half as many deaths as its far more frequent competitor, acute appendicitis with sequelae, and assigns to it a mortality of 40 to 60 per cent in the United States in 1944. Colcock¹³ terms it "the most serious lesion affecting the small bowel." Stone and Owings¹⁴ write that the results of its treatment are unsatisfactory and that the mortality is unnecessarily high. Dennis and Brown¹⁰ in 1943 summarized the general mortality up to the time of their report as 18 to 20 per cent in skilled hands. Thus, the gravity of this problem is emphasized directly or indirectly by all authors, and it is undeniable that the problem of management of these patients is far from solved. The tragedy of such

mortality, depressing mortality figures are to be expected.

Before what might be called the "Wangensteen era," the last decade or so—the prognosis of acute intestinal obstruction was truly grave. Miller¹ reported a mortality of 61 per cent in 1929. Cole² states that the mortality of two decades ago was 30 to 40 per cent. Bennett³ states that a 70 per cent mortality prevailed in earlier days. Moreover, a survey of the more recent literature reveals that

results must be even more apparent when it is realized that many patients represent the final harvest of trivial, even at times unnecessary, previous exploratory operations.

During the last fifteen years great forward strides have been made in the management of these problems. These have been accomplished through such procedures as the Wangenstein^{6, 15} suction method, the Miller-Abbott¹⁶ intubation method, Fine's¹⁷ oxygen decompression method and the liberal use of parenteral fluids, blood and plasma.^{2, 8, 9, 11, 18-20} to mention the more dramatic advances

vanced physiological age as compared with the chronological age and, possibly most important of all, the educational deficiencies that bring them to medical care late in the course of their diseases. When these handicaps are compounded with an illness that in the best of hands carries a formidable

this condition is still one of the most serious seen by the surgeon.

It appears from an analysis of such results as are reported that a rate of about 20 per cent is a reasonable goal at which to aim. To illustrate this consensus, the mortality rates from some leading clinics are presented in Table 1.

Richardson¹² indicts acute obstruction for causing half as many deaths as its far more frequent competitor, acute appendicitis with sequelae, and assigns to it a mortality of 40 to 60 per cent in the United States in 1944. Colcock¹³ terms it "the most serious lesion affecting the small bowel." Stone and Owings¹⁴ write that the results of its treatment are unsatisfactory and that the mortality is unnecessarily high. Dennis and Brown¹⁰ in 1943 summarized the general mortality up to the time of their report as 18 to 20 per cent in skilled hands. Thus, the gravity of this problem is emphasized directly or indirectly by all authors, and it is undeniable that the problem of management of these patients is far from solved. The tragedy of such

mortality, depressing mortality figures are to be expected.

Before what might be called the "Wangensteen era," the last decade or so—the prognosis of acute intestinal obstruction was truly grave. Miller¹ reported a mortality of 61 per cent in 1929. Cole² states that the mortality of two decades ago was 30 to 40 per cent. Bennett³ states that a 70 per cent mortality prevailed in earlier days. Moreover, a survey of the more recent literature reveals that

results must be even more apparent when it is realized that many patients represent the final harvest of trivial, even at times unnecessary, previous exploratory operations.

During the last fifteen years great forward strides have been made in the management of these problems. These have been accomplished through such procedures as the Wangensteen^{6, 15} suction method, the Miller-Abbott¹⁶ intubation method, Fine's¹⁷ oxygen decompression method and the liberal use of parenteral fluids, blood and plasma.^{2, 8, 9, 18-20} to mention the more dramatic advances

*From the Surgical Service of the Gallinger Municipal Hospital.

†Chief surgical resident, Gallinger Municipal Hospital.

Each of these valuable adjuncts, however, has been enthusiastically ushered in, only to be later ranked as falling far short of being the unmixed blessing it seemed at first. Certainly, few can deny that the efficient care of obstructed patients calls for nicety of judgment, assiduous and diligent attention and individualization hardly demanded by any other group. Such cases do not lend themselves to standardization by any known therapeutic scale. It is with this precept in mind, rather than varying formulas of duration of obstruction, objective findings of abdominal tenderness, rigidity and the like or white-cell counts, that one should attempt to treat these patients.

Any series of acute intestinal cases with an unusually low mortality of necessity demands an accounting of the methods of diagnosis employed. Little question of diagnostic accuracy is encountered in the patients receiving operations, the finding in whom of obliteration of a section of bowel lumen, with dilatation of the bowel above and its collapse below the point, eliminates argument concerning classification. Justifiable critical scrutiny, however, may be aimed at the cases not operated on. Only one of our patients with hernial obstructions was not operated on, the ultimate diagnosis being confirmed at autopsy. This method of confirmation was applied to a case of obstruction due to a metastatic malignancy and to another due to mesenteric vascular occlusion. With the exception of these

admission and after two or more irritating enemas, typical peristalsis and roentgenologic demonstration of distended bowel, with fluid levels and absence of colonic gas. Failure to demonstrate any one or more of these diagnostic points has excluded many cases from the series.

Paramount in the criteria for judging the method of handling these problems is an assessment of the general condition rather than the local disease. We fear, as do all surgeons, the progression of bowel changes from obstruction to strangulation and finally to loss of viability, but we also believe these to be relatively overemphasized. We are convinced that it is better to operate on many of these patients six, eight or ten hours later, when they can tolerate the procedure, than to perform a possibly simpler and easier operation at once when they are too ill to stand it. We believe that it is safer to consider every patient with intestinal obstruction as critically ill and as a truly poor-risk patient, one who is actually too ill to withstand the operation that he nonetheless may require. Therefore, we do not allow our natural fear of local bowel change to carry the same weight as concern for the patient's general condition. The former is more obvious, more easily demonstrated and more readily evaluated, but the latter constitutes the greater threat to life.

Our method of treating acute obstruction of the small bowel is to provide surgical correction of the

cases and of those due to adhesions, all our diagnoses were confirmed at operation. Concerning the cases due to adhesions, the presence of complete obstruction may be difficult to decide with certainty without operation, and many patients who were treated conservatively have been omitted from this survey because there was a lack of one or more absolute criteria for the conclusion that obstruction was complete. Of this group of patients, 22 satisfied our criteria by the demonstration of intermittent, cramping abdominal pain, repeated vomiting, failure to pass gas or feces by rectum prior to

condition when the patient has reached the peak of general systemic improvement. Of course, some of these patients seek hospital care quite early in their illness, often permitting immediate surgery, but their number in municipal institutions is notably small. Even this group, however, receives what might be called prophylactic treatment for shock, intubation, suction and blood or plasma before and during operation, despite their apparently satisfactory condition on admission. The other, much larger, group demands an exhaustive study to assess its ability to counter the shocking effect of the

contemplated operation. It is difficult to make blanket recommendations for judging this ability, but generally speaking we favor postponing surgery until the pulse is stabilized below 110, the blood pressure is at normal or near-normal limits, the acid-base balance is restored, as estimated by the type of respiration, the plasma carbon dioxide combining power, acetonuria, dermation of the serum sodium and chloride levels and so forth, hydration has been achieved, as determined by the appearance and feel of the tongue, blood urea nitrogen studies, the specific gravity and quantity of urine passed during preparation and hematocrit studies, the definitive treatment of complications, such as pneumonia and heart failure, is well under way, there is significant improvement in distention, and the general effects of shock — sweating, pallor or cyanosis, coldness of the extremities and mental torpor or severe anxiety — have been alleviated.

To illustrate the importance and frequent association of these factors in the present series, certain facts are of interest. Of the 90 patients undergoing operation, only 9 (10 per cent) were admitted with pulse rates below 90. Eleven (12 per cent) were admitted with a pulse in excess of 120 and a systolic blood pressure below 100. Three (3 per cent) were admitted with no radial pulse or blood pressure detectable. Of these, 1 patient, a fifty-eight-year-old man with a strangulated inguinal hernia of eight days' duration, died. He was operated on after six hours of preparation with a systolic blood pressure of only 80 because no more blood or plasma was available. This was the only patient in this group of 11 admitted in shock who had not been restored from it before operation.

At this point there arises the question so often propounded concerning the hypothetical patient who does not respond favorably to the giving of blood or plasma, suction and so forth during the preparative period. These conditions exist very rarely when *enough* preparation is given. Even in the 3 patients with complete occlusion of the superior mesenteric artery, only 1 failed to respond favorably and was therefore not operated on. A girl of seventeen, who had had obstruction from postinflammatory adhesions for fourteen days, required 4800 cc of blood and plasma in eighteen hours to stabilize the pulse and blood pressure and who was mistakenly declared dead by an intern shortly after admission, had an uneventful postoperative course. Even the rare patient who does not respond leaves one no alternative, however, since an anesthetic and a major operation would certainly not alleviate the state of shock.

Only 9 patients (10 per cent) were admitted within twenty-four hours of the onset of obstruction, as contrasted with 44 per cent reported by Dennis and Brown,¹⁰ with a 78 per cent mortality. There was no mortality in our comparable group.

Disturbances in acid-base balance were almost the rule, being evidenced by acetonuria, depletion of serum chloride and so forth in 86 per cent of the cases tested. Major degrees of dehydration, manifested by a dry tongue, scanty and concentrated urine, excessive blood concentration and elevated blood urea nitrogen, were observed in 43 per cent of the series. Four patients (4 per cent) had pneumonia complicating the obstruction, 5 (6 per cent) had coincident cardiac failure, and 3 others had a systolic blood pressure in excess of 200.

From these data it will be seen that the recent recommendations for early or immediate operation^{3, 8, 12, 14, 16, 21, 22} could not be applied to the type of patient seen in this hospital. The operation for intestinal obstruction, however simple, is made on a patient poorly constituted to tolerate it, who requires a considerable amount of care to provide reasonable assurance of his survival.

During the period from January 1, 1943, to March 1, 1945, a total of 118 cases of small-bowel obstruction were observed (Table 2). Ten of these patients died, a mortality of 8 per cent. Ninety patients were operated on, and 7 of these died, a mortality of 8 per cent. In 14 patients resection was necessary, and 3 of these died, a mortality of 21 per cent. The operations in all cases with resection, with one exception, consisted of a primary anastomosis of the aseptic type. In 2 of the fatal cases, massive gangrene of the small bowel, caused by mesenteric vascular occlusion, was found, but resection was not performed.

SUMMARY AND CONCLUSIONS

One hundred and eighteen cases of acute complete small-bowel obstruction seen in a large municipal hospital, 90 of whom were treated operatively, are presented. Data of interest on these patients are given.

The generally high mortality in this group, from several decades past to recent reports from leading clinics, is reviewed.

The necessity for evaluation of the patient as a whole rather than placing undue emphasis on local bowel disease is stressed.

A warning note is sounded against the preponderant recent advocations of immediate operation on these severely ill patients, and a plan for evaluating the proper time for operation is presented.

The general nature of the systemic condition of these patients is summarized.

Of the 118 patients treated, 10 died, a mortality of 8 per cent. Of the 90 operated on, 7 failed to survive, an operative mortality of 8 per cent.

EPISTAXIS*

HENRY H AMSDEN, M D

CONCORD, NEW HAMPSHIRE

NOSEBLEED is of frequent occurrence, often stops spontaneously and in the great majority of cases is easily controlled. It may, however, be extremely persistent and, although seldom endangering life, may cause much anxiety to both patient and physician.

In the event of persistent or recurring attacks, a search should be made for some underlying cause, such as hemophilia, leukemia, anemia or diabetes. This type of nosebleed also frequently occurs in hypertension in elderly people and in affections caused by hemolytic streptococci. It should be regarded as a surgical condition, and the usual measures should be taken for its control, through direct pressure, cauterization or cutting off the blood supply to the bleeding point, by ligation or otherwise.

A study of the anatomy of the blood supply of the nose affords a more intelligent approach to treatment. The sphenopalatine artery is a branch of the internal maxillary, which in turn is derived from the external carotid. This artery comes through the sphenopalatine foramen, and its terminal branches are distributed over the septal and lateral walls of the nasal cavity. A large branch runs along the floor of the nose and anastomoses with the great palatine artery through the incisive foramen.

A large majority of spontaneous hemorrhages occur from the so-called "Kisselbach's area," an arteriovenous plexus on the anteroinferior portion of the cartilaginous septum. These vary from simple oozing, easily controlled by pressure, to active arterial bleeding from a small vessel.

Various means of control have been advocated, among them pressure with packs saturated with hydrogen peroxide or adrenalin, the application of salt pork, fresh tonsillar tissue, snake venom and various hemostatic preparations and the submucous injection of novocain. The use of an inflated glove finger has also been suggested.

The simplest and most efficient method, when the bleeding point can be readily seen, is direct cauterization of the anesthetized mucous membrane. Care should be taken not to burn too deeply, thus perforating the opposite nostril. In some cases of mild bleeding a crystal of chromic acid fused on a metal applicator is sufficient.

The most annoying type of bleeding comes from some point that cannot readily be seen, and for which other means of control must be adopted. Bleeding may occur from a point on the posterior surface of a septal deviation not accessible to cauterization, this can be controlled by submucous resection. In recurring bleeding from Kisselbach's area, it may be unwise to repeat cauterization, and submucous elevation of the mucoperichondrium may be necessary.

Most spontaneous hemorrhages — that is, those of the nontraumatic variety — seem to come from a point below the level of the inferior turbinate, they seldom arise from the upper portion of the nasal cavity. The postnasal plug, sometimes necessary, is extremely annoying to the patient and may lead to infection of the middle ear or sinuses, the plug should ordinarily not be left in place for more than twenty-four hours. The best method of inserting it is as follows. A soft catheter introduced through the bleeding nostril is drawn out through the mouth, and a double string is attached to the

*Presented at the annual meeting of the New Hampshire Medical Society Manchester, May 15 1945

catheter and withdrawn through the nose, pulling the plug into place. The nostril should be tightly packed and the double string tied over a sponge, a third short string attached to the plug facilitates its removal through the mouth.

Before resorting to this method, an effort should be made to locate more accurately the source of the bleeding. As already stated, most of these hemorrhages seem to come from a point below the lower turbinate. It is difficult to pack gauze into this area, and a useful procedure is to introduce several wooden applicators wound with cotton and saturated with adrenalin or cocaine, this in itself often stops the bleeding and helps to locate its source. The applicators may be left in place for some time if desired.

Reference to the blood supply of the nose shows that the largest arterial vessel is the anastomosis between the sphenopalatine and great palatine arteries through the incisive foramen, and it is at this point

that persistent hemorrhage may occur. In fact, active pulsation is often seen here, at a point inaccessible to cauterization. A method that has proved successful in meeting this situation is submucous elevation of the tissue on the floor of the nose and lower meatus. Under novocain anesthesia an incision is made at the mucocutaneous juncture, allowing the insertion of a sharp submucous elevator carrying the separation back beyond the incisive foramen, thus shutting off the blood supply. If necessary, a small gauze pack may be inserted between the soft tissues and the bone. In case the hemorrhage cannot be controlled in the manner suggested, it may be necessary to tie off the external carotid artery.

SUMMARY

Methods for the control of persistent or recurring epistaxis are reviewed.

CARDIOVASCULAR DISEASE AMONG VETERANS OF WORLD WAR II*

A Survey of 19,870 Cases

MAJOR AARON H. TRAUM, M.C., A.U.S.,† AND BLANCHE B. WILCOX, Ph.D.‡

With the technical assistance of the Office of Budget and Statistics

WASHINGTON, D.C.

THERE are many gaps in the knowledge of heart disease, the leading cause of death among adults in the United States. To follow a case of cardiovascular disease from its earliest recognized manifestations throughout the lifetime of the patient may lead to a better understanding of such disease processes. Furthermore, there is a distinct need for more information concerning the natural history of circulatory disturbances that apparently commence or exhibit their first signs and symptoms in young adults. The relation of race, sex, age, place of residence and similar factors to various types of heart disease can best be appraised by analyzing and following large numbers of cases in each disease category.

At the present time, an unusual opportunity for such a study is available to the Veterans Administration in the large groups of veterans of World War II who have been discharged from the armed forces because of cardiovascular disease. This source material is of potential value for the following reasons. First, there is available a select group of patients of military age who one or two years previ-

ously were considered physically acceptable for active military service. Second, in most cases the disease was carefully observed at its inception or evaluated during its development in military service, and the patients, as beneficiaries of the Veterans Administration, will be followed through the course of the disease to its termination. Third, the medical data available for analyses are adequate, since they include induction medical examinations, medical records of hospitalization during military service and Veterans Administration medical examinations made in outpatient departments or during periods of hospitalization following separation from military service. Lastly, these veterans live in all sections of the United States.

The present study was restricted to veterans with service-connected cardiovascular disabilities incurred in or aggravated by military service on or after December 7, 1941, who were on the Veterans Administration pension rolls up to June 30, 1944. These patients, the majority of whom have not been treated in hospitals of the Veterans Administration, comprised the largest group of cardiovascular cases among World War II veterans available for analysis.

There are three other groups of veterans with circulatory abnormalities whose cases are not included in this report and are the subjects of papers now in preparation. The first group comprises vet-

*From the Cardiovascular Research Unit, Veterans Administration Facility.

†This report is published with the permission of the medical director of the Veterans' Administration who assumes no responsibility for the opinions expressed or the conclusions drawn.

‡Chief, Cardiovascular Research Unit, Veterans Administration Hospital.
§Medical statistician Cardiovascular Research Unit Veterans Administration Hospital.

erans whose disability rating claims were disallowed and who do not receive pensions and are considered as non-service-connected. In most of these cases, the cardiovascular disability was considered to have existed prior to induction and not to have been aggravated by military service. The second group is composed of patients, whether or not service-connected, who have received hospital care from the Veterans Administration. The third group includes reserve officers receiving retirement pay for cardiovascular disabilities.

The cardiovascular diagnoses used as a basis for this study were obtained from the reports of the disability boards of the Veterans Administration.

recorded. An accurate racial classification was made in 18,148 patients (Table 2). Of these, 16,065 (80.8 per cent) were Whites, 1,987 (10 per cent) were Negroes, and 96 (0.5 per cent) were of other races. In the 1,722 remaining cases, the racial factor was not clearly stated.

There were 19,789 men and 81 women.

DIAGNOSES

Valvular Heart Disease

The diagnosis of valvular heart disease with no etiologic factor designated was the most frequent one, being made in 5,774 cases (29.1 per cent). The ages of these patients ranged from seventeen to

TABLE 1 *Distribution of Cases according to Diagnosis and Age*

These boards obtained the diagnoses either directly from the findings of the medical officers who had treated or observed the veterans immediately preceding their discharge from the armed forces or from subsequent physical examinations conducted by the medical officers of the Veterans Administration. Most of these examinations included detailed histories, physical examinations, roentgenograms of the chest, electrocardiograms and the routine laboratory procedures, as well as many special ones.

A preliminary survey of 19,870 World War II veterans with cardiovascular disease was undertaken to appraise some of the available material for the purpose of developing practical follow-up programs. The data obtained were analyzed from the viewpoints of age, sex and race, diagnosis and geographical distribution, and the trends revealed were considered of sufficient interest to report at this time.

AGE, RACE AND SEX DISTRIBUTION

The ages ranged from seventeen to sixty-five years, with an average of 29.5 years (Table 1). Eleven thousand, three hundred and sixty-one patients (57.2 per cent) were under thirty years of age, 6,254 (31.5 per cent) were between thirty and thirty-nine and 2,171 (10.9 per cent) were forty years of age or older. In 84 cases the age was not

recorded. An accurate racial classification was made in 18,148 patients (Table 2). Of these, 16,065 (80.8 per cent) were Whites, 1,987 (10 per cent) were Negroes, and 96 (0.5 per cent) were of other races. In the 1,722 remaining cases, the racial factor was not clearly stated.

There were 19,789 men and 81 women. The distribution of the various valvular lesions in this group was interesting. Lesions limited to the mitral valve were diagnosed in 3,646 cases, there was mitral insufficiency in 2,273, and a mitral stenosis, with or without insufficiency, was present in

TABLE 2 *Distribution of Cases according to Race and Sex*

RACE	MEN		WOMEN		TOTALS	
	NO OF CASES	PER- CENTAGE	NO OF CASES	PER- CENTAGE	NO OF CASES	PER- CENTAGE
Whites	15,994	80.8	71	87.7	16,065	80.8
Negroes	1,982	10.0	5	6.2	1,987	10.0
Others	95	0.5	1	1.2	96	0.5
Race not reported	1,718	8.7	4	4.9	1,722	8.7
Totals	19,789		81		19,870	
Percentages		99.6		0.4		

1373. Involvement of the aortic valve alone was reported in 1,029 cases, the predominating lesion was diagnosed as aortic insufficiency in 859, and as aortic stenosis in 170. Combined aortic-valve and mitral-valve lesions, including various combinations of involvement, were diagnosed in 971 cases. The diagnosis of chronic endocarditis without reference to the valves involved was made in 120 cases, and tricuspid-valve and pulmonic-valve lesions were each diagnosed in 4 cases.

Rheumatic Fever

Rheumatic fever was diagnosed in 2981 cases (15 per cent). The average age was 25.6 years, the lowest average encountered in any of the groups. Two thousand, three hundred and ninety-three patients (80.0 per cent) were under thirty years of age, and 2888 (96.8 per cent) were under forty.

Rheumatic fever without any recognized or diagnosed myocardial or valvular residuals occurred in 813 cases (27.4 per cent), valvular disease in 1853 cases (62.1 per cent), and rheumatic myocarditis or pericarditis in 315 (10.5 per cent).

The distribution of lesions among the 1853 cases of valvular disease was as follows: mitral lesions alone, 1423 cases, aortic and mitral lesions combined, 197 cases, aortic lesions alone, 150 cases, and valvular disease with the involved valves not identified, 83 cases. Mitral insufficiency was diagnosed as the main valvular abnormality in 1175 cases, and mitral stenosis, with or without insufficiency, in 248 cases. Among the lesions of the aortic valve alone, the main anatomic lesion was aortic insufficiency in 128 cases and aortic stenosis in 22.

Hypertension

Hypertension was considered to be the etiologic factor responsible for the main disability of 2945 patients (14.8 per cent). Essential hypertension and hypertension with an associated cardiac disease, with or without the additional factor of coronary arteriosclerosis, are included in this category. The average age of all of the patients in this classification was 31.5 years, with a range of nineteen to sixty-one years. The large number of young people affected is noteworthy. One thousand, two hundred and seventy patients (43.1 per cent) were twenty-nine years of age or younger, and 1309 (44.4 per cent) were between thirty and thirty-nine.

Peripheral Vascular Lesions

Peripheral vascular disease other than arteriosclerosis was found in 2563 cases (12.9 per cent). Six clinical entities were included in this group, with an over-all average age of 31.4 years and an age range of eighteen to fifty-seven years. Varicose veins, thrombophlebitis and chronic phlebitis accounted for 2304 (89.9 per cent) of the peripheral vascular lesions. The remaining 259 cases were distributed as follows: thromboangitis obliterans, 127 cases, Raynaud's disease, 108 cases, and arteriovenous fistula, 24 cases.

Arteriosclerosis

Arteriosclerosis was considered to be the etiologic factor in 1733 cases (8.7 per cent). As was expected, the average age (38.8 years) was the highest in any group studied, with a range of nineteen to sixty-five years. Nine hundred and ninety-one (57.2 per cent) of the patients were considered as having coronary arteriosclerotic heart disease and revealed

an average age of 39.9 years, as compared to 37.8 years in the 742 cases diagnosed as arteriosclerosis without any definite statement concerning cardiac involvement.

The most interesting feature in this group was the large number of young men affected and the high incidence of coronary-artery occlusion. Of the 991 patients with coronary arteriosclerotic heart disease, 491 (49.5 per cent) were under forty years of age, 389 were between thirty and thirty-nine, and 235 were under thirty-five. Three hundred and fifty-seven patients (36 per cent) were diagnosed as having coronary-artery occlusion or myocardial infarction. Of these, 236 were under forty years of age and 177 were in the fourth decade, with 137 under thirty-five.

Neurocirculatory Asthenia

Neurocirculatory asthenia was diagnosed in 1255 cases (6.3 per cent). The average age was 29.1 years, and the range was nineteen to fifty-seven years. The majority of cases were in young men, with 708 (56.4 per cent) under thirty years of age and 1203 (95.8 per cent) under forty. Many cases were undoubtedly lost sight of because this syndrome was considered or diagnosed as a part of other clinical entities.

Miscellaneous Diseases

Eight diseases of the heart and blood vessels were grouped under a single classification. These affected 865 patients, whose average age was 31.1 years, with a range of eighteen to sixty-five years. This category was composed as follows: arrhythmias, 397 cases, angina pectoris, 200 cases, cerebral vascular lesions, 128 cases, pericarditis, with or without effusion, 69 cases, lesions of the aorta, 31 cases, congenital heart disease, 26 cases, acute myocarditis, 13 cases, and periarteritis nodosa, 1 case.

The etiology of the cases of arrhythmia and pericarditis was either not given or did not allow of segregation into other classifications. In the 200 cases of angina pectoris there was no mention of any associated etiologic or anatomic diagnosis. It is noteworthy that the age distribution of this small subgroup closely paralleled that of the larger arteriosclerotic group. The 128 patients with cerebrovascular lesions showed an average age of 31.5 years, with a range of nineteen to fifty-one years. There were three types of these lesions in which no etiologic factors were designated—namely, cerebral hemorrhage, 72 cases, cerebral thrombosis, 40 cases, and cerebral embolism, 16 cases. The 31 cases of aortic lesions without a definite etiologic agent were diagnosed as either aortic dilatation or aortic aneurysm. The 26 cases of congenital heart disease were considered to have been aggravated by military service. The diagnoses were as follows: patent ductus arteriosus, 7 cases, coarctation of

he aorta, 6 cases, interauricular septal defect, 2 cases, and unclassified congenital heart disease, 11 cases. The etiology was determined in all 13 cases of acute myocarditis, of which 3 were considered as due to direct trauma and 10 as secondary to identified severe infectious processes.

Nonvalvular Heart Disease of Unknown Etiology

In 1754 cases (8.8 per cent), nonvalvular cardiac damage was diagnosed without reference to the etiologic factor. Chronic myocarditis, myocardial damage and cardiac degeneration were the conditions most frequently diagnosed, occurring in 1714 cases. Cardiac hypertrophy was diagnosed in 38 cases, and cardiac dilatation in 2 cases. The average age in this group was 30.7 years, with a range of eighteen to sixty-three years.

GEOGRAPHICAL DISTRIBUTION

An analysis was made of the geographical distribution — by residence — of patients with cardiovascular disabilities, for the sole purpose of evaluating on a regional basis the follow-up potentialities of each of the discussed classifications (Table 3).

TABLE 3 *Distribution of Cases according to Diagnosis and Residence*

	NEW ENGLAND		MID-ATLANTIC		SOUTHERN		MID WESTERN		WESTERN		UNKNOWN OR OUTSIDE U S A		TOTAL	
	NO OF CASES	PER-CENTAGES	NO OF CASES	PER-CENTAGES	NO OF CASES	PER-CENTAGES	NO OF CASES	PER-CENTAGES	NO OF CASES	PER-CENTAGES	NO OF CASES	PER-CENTAGES	NO OF CASES	PER-CENTAGES
Valvular heart disease	451	7.8	1,491	25.8	1,205	20.9	1,908	33.1	704	12.2	15	0.2	5,774	29.1
Rheumatic fever	213	7.2	578	19.4	660	22.1	985	33.0	542	18.2	3	0.1	2,981	15.0
Hypertension	135	4.6	733	24.9	875	29.7	950	32.2	250	8.5	2	0.1	2,945	14.8
Peripheral vascular lesions	204	8.0	617	24.1	601	23.4	844	32.9	292	11.4	5	0.2	2,563	12.9
Arteriosclerosis	122	7.0	493	28.5	444	25.6	432	24.9	232	13.4	10	0.6	1,733	8.7
Neurocirculatory asthenia	53	4.2	286	22.8	352	28.1	464	37.0	97	7.7	3	0.2	1,255	6.3
Miscellaneous diseases	46	5.3	207	23.9	213	24.6	294	34.0	103	12.0	2	0.2	865	4.4
Nonvalvular heart disease (etiology unknown)	92	5.3	437	24.9	505	28.8	489	27.9	226	12.9	5	0.3	1,754	8.8
Totals	1,316		4,842		4,855		6,366		2,446		45		19,870	
Percentages		6.6		24.4		24.4		32.1		12.3		0.2		
Veterans on pension rolls	6,758		57,463		55,624		64,963		22,799		912		208,519	
Percentages of veterans on pension rolls		3.2		27.6		26.7		31.2		10.9		0.4		
Percentages of population (U S 1940 census)		6.4		23.0		27.4		32.7		10.5				

A fairly close agreement on a percentile basis was noted between the total series of cardiovascular cases and almost all its component groups, with the total population taken as that of the 1940 national census. It must be emphasized that this distribution refers only to the home residence in June, 1944, and in no way indicates the location of the origin or development of the various disease entities.

DISCUSSION

The grouping of the various cardiovascular conditions incorporated in this report was not entirely satisfactory. The classification was based on the

information listed in the diagnoses used during the consideration of the veteran's first disability rating claim and were obtained from several sources, that is, the Army, the Navy and the Veterans Administration, each of which employed a different nomenclature. This made difficult the arrangement of such data in sharply delineated groups on the bases of etiologic or anatomical findings.

A more precise classification will be possible when the diagnoses are based on a uniform system of criteria and nomenclature. In the groups in which the etiology was not stated, many of the cases will be more appropriately designated. In the large group now considered as that of valvular heart disease, many cases will be reclassified as those of rheumatic heart disease. Obviously, practically all the cases of mitral stenosis and many of the cases in which the diagnosis was limited to aortic valvular disease and combined aortic and mitral valvular disease could be placed in the rheumatic group, this was not done in this survey unless the etiologic factor was stated in the diagnosis. In the rheumatic-fever group, the cases of actual cardiac disease will be more accurately separated from those of rheu-

matic fever without recognized evidence of myocardial or valvular damage, likewise, the hypertensive cases, with or without myocardial involvement, will be segregated. In any follow-up program the patients with rheumatic fever or systemic hypertension without evidence of any cardiac involvement should be classified as having potential heart disease — a separation that, at the present time, the wide variations in the nomenclature render impossible.

Study of the geographical distribution by residence showed that the various cardiovascular conditions were widely distributed throughout the Nation. This may ultimately prove of some value in apprais-

ing the effects of residence in various sections of the country on each disease entity as these cases are followed during the ensuing years

SUMMARY

A survey of cardiovascular disease among 19,870 veterans of World War II on the Veterans Administration pension rolls as of June 30, 1944, has been reported. All the data were obtained from the reports of the diagnoses used in the evaluation of the pension claims of veterans.

The various cardiovascular conditions were classified in eight groups, based on information available

from these diagnoses, which originated from sources employing several different nomenclatures. The numbers of cases in each group were as follows: valvular heart disease with no etiologic factor mentioned, 5774 cases, rheumatic fever, with or without cardiac involvement, 2981 cases, hypertension, 2945 cases, peripheral vascular conditions, 2563 cases, arteriosclerosis, with or without cardiac involvement, 1733 cases (including 991 cases specifically designated as coronary heart disease), neurocirculatory asthenia, 1255 cases, miscellaneous diseases of the heart and blood vessels, 865 cases, and cardiac lesions other than valvular conditions, without a recognized etiologic factor, 1754 cases.

SYMPOSIUM ON MEDICAL SOCIOLOGY

HEALTH-INSURANCE PLANS*

NATHANIEL W. FAXON, M.D.†

DOCTORS and hospitals cannot maintain a policy of isolationism in modern society any more than can governments and countries in the present economic world. The study of the interdependent relations that result is called "medical sociology." Today we are to explore some of the problems of medical sociology involving hospitals, but we shall soon discover that there are no watertight compartments in medical sociology, and that a study of hospital problems immediately involves doctors, patients and prospective patients.

The subject of this lecture is clear in its intent, as is the main objective — namely, better medical care at costs that can be borne. There is disagreement, however, as regards means.

Let us avoid in this connection such terms as "socialized medicine," "regimentation," "totalitarian control," "rugged individualism," "medical trust" and similar catch phrases, and stick to terms that will be enlightening without developing heated controversy.

THE PRESENT SITUATION

As a foundation for the consideration of this subject, it will be well to review the present situation regarding physicians, hospitals, insurance and federal or state agencies dealing with health and sickness.

Physicians are licensed by state boards to practice medicine, either individually or in groups. They may or may not be on hospital staffs. They may be on a salary basis in a medical school, hos-

pital or industry or in a federal or state department.

Hospitals are divided into governmental hospitals — federal, state, county and city — supported by taxation, voluntary — charitable or non-profit — hospitals supported in other ways than taxation, proprietary or private hospitals intended to be profit-making, and lastly, hospitals supported by industrial companies for the benefit of their employees. All but a few of the mental, tuberculous and chronic patients are cared for in state hospitals. Ex-servicemen in these classes are cared for in federal veterans' hospitals. There are many municipal general hospitals, and most communicable-disease hospitals are tax-supported.

There are also the United States Public Health Service and the various state departments of health, with whose duties everyone is familiar. The federal government conducts the equivalent of industrial accident insurance for federal employees. There are the Children's Bureau and its Emergency Maternity and Infant Care Program, as well as the Old-Age Insurance and Care of Crippled Children programs of the Federal Security Agency. In Massachusetts there are the Industrial Accident Board, the welfare departments of state, cities and towns, the Division of the Blind and no doubt many others.

It is thus evident that there is already an extremely wide participation by government in medical affairs and that a large amount of tax funds goes into these activities. It seems axiomatic that any further extension should be built on this framework, complementing and supplementing rather than replacing existing agencies. This is important to keep in mind.

*This is the third of a series of nine lectures on medical sociology given weekly at Harvard Medical School during January, February and March 1945, they were sponsored by the Department of Preventive Medicine and were primarily intended for third year students.

†Director, Massachusetts General Hospital and Massachusetts Eye and Ear Infirmary.

Most insurance companies pay a cash indemnity to the subscriber to cover hospital costs or medical fees. The Blue Cross supplies a service payment by paying hospital charges. There is a great difference between these. The cash indemnity may or may not cover hospital charges, and in the latter case the balance of cost must be borne by the patient or the hospital. Moreover, the indemnity is paid to the individual, who may or may not pay the hospital. Service payment does cover the hospital charges up to the period of hospitalization granted, which is thirty days, with a 50 per cent reduction for ninety days more. This payment, of course, covers all but the most unusual cases. It is made to the hospital.

BASIC STATEMENTS

All consideration of this subject should begin with a reading of the report of the Committee on the Costs of Medical Care, published in 1932, which presents the results of careful research and considered opinions based on them. Since the issuance of this report many other studies have been made, and out of all these have come the following generally accepted facts.

There are four groups of persons in the population. The first group includes the rich or well-to-do, who have ample resources to meet the costs of medical and hospital care, with annual incomes of \$5000 or over. They form 9.2 per cent of the population. The second group is the upper middle class, with annual incomes of \$2000 to \$5000, forming 35.2 per cent of the population. Voluntary Blue Cross plans have appealed to this group. The third group is that of the wage earners, with annual incomes from \$1000 to \$2000, forming 41.0 per cent of the population. The fourth group comprises the indigent, persons with annual incomes below \$1000, forming 14.0 per cent of the population.

Estimates of the cost of medical care vary, but it is somewhere between \$25.30 and \$66.97 for the provision of adequate medical care — that is, house, office and hospital care by physician and nurse, hospital care and to some extent dental care.

It is generally accepted that if people would pay into an insurance plan all the money they now pay to doctors, hospitals and nurses, together with what they spend on medicines, including patent medicines, full medical hospital and nursing care could be provided without further expenditure. But no one is naïve enough to believe that things will work out in this way.

On certain points there is general agreement. First, medical care is costly. Sickness is unpredictable, regarding both the persons affected and its frequency and length. There is need of some method to spread this cost, either by insurance or by taxation. Second, hospitals and doctors are concentrated in cities and scarce in rural areas. There is need to even this imbalance. Hospitals should be

built in isolated places and doctors subsidized to practice there. Third, more medical care would be advantageous, especially in the field of preventive medicine. The poor get less care than they need, and the rich probably pay more for such care than they should. Fourth, medical education must be carried beyond graduation from medical school. Lastly, research must be supported.

PRESENT INSURANCE PLANS

Until recently, sickness has been regarded as something to be handled when it occurs. This attitude has been attacked from the medical side through the development of preventive medicine, and from the social side through the development of prepayment plans or the application of the insurance principle.

Voluntary Insurance

Commercial insurance companies. Insurance companies have for a long time sold accident insurance and, in a small way, sickness insurance with cash indemnity, the latter being handled as a sideline of life insurance. Now, however, since insurance against the costs of medical and hospital care are arousing interest, many insurance companies are offering policies similar to those of the Blue Cross and Blue Shield, except for the fact that they provide for cash indemnity.

The Workmen's Compensation Act is a form of insurance against industrial accidents and sickness.

The Blue Cross. The Blue Cross was developed to provide a means of spreading the cost of hospitalized illness through prepayment on the insurance principle. It began in Dallas, Texas, in 1932 in a limited way to provide care in the University Hospital for teachers in Baylor University, and rapidly spread to other sections of the population of that city. With the interest and support of the American Hospital Association, certain principles of operation were developed and published. There are now eighty plans in thirty-eight states, with over 16,000,000 subscribers.

The Massachusetts Blue Cross, started five years ago, has 1,000,000 subscribers. The plan is based on actuarial figures showing that of every 10 persons one is hospitalized each year for a period of slightly less than ten days — (just under eight for men and just over eight for women). It is thus estimated that for every 1000 persons insured there will be about one thousand days of hospital care.

The success of the Blue Cross is due to the fact that it meets a need in a practical way. It is a non-profit organization and is safeguarded by coming under the direction of the State Commissioner of Insurance. The governing body is composed of sixteen directors, a majority of whom must be trustees, directors or staff members of hospitals, the remainder being representatives of the Massachusetts Medical

Society and selected representatives of industries whose employees are insured

It is preferable to insure under the group method, since thereby no physical examination is necessary because the undesirable risks are automatically cancelled. Sixty per cent of the employees of any group of 50 or more must be enrolled, below this number a higher percentage must participate. Individual subscribers can be enrolled by submitting to a physical examination, for which they pay. The cost of membership is \$10.00 a year for single persons, \$19.80 for a husband and wife and \$24.00 for a family, regardless of the number of children.

The Blue Cross collects money from its subscribers, issues certificates of membership, makes contracts with hospitals and pays the hospital charges of its members. The hospital makes to the Blue Cross exactly the same charges, with a few exceptions, that it would render to an ordinary patient, but with a maximum daily charge of \$6 for thirty days. As previously stated, if hospitalization is continued beyond this period, the Blue Cross pays 50 per cent of the hospital charges for ninety additional days.

Blue Cross plans are quite satisfactory so far as hospitalization goes, since they are inclusive, economical and widely available.

The Blue Shield

The success of hospital-insurance plans has led to a demand for similar insurance to cover professional fees for hospital illnesses. To meet this demand, organizations have been set up and sponsored by state and other medical groups. They were started later than the Blue Cross but are now operating in thirteen states, containing 50 per cent of the population of the United States. The largest unit is in Michigan.

The Blue Shield, the name applied to the corporation founded by the Massachusetts Medical Society, was formed in June, 1943. It insures single persons with annual incomes up to \$2000 and families with incomes up to \$2500 and pays their doctors' fees for surgical or obstetric care in hospitals. The doctors participating in this plan accept a standard fee for operations and obstetric care. About 88,000 persons are now enrolled. The cost of membership is \$10.00 a year for single persons, \$19.80 for a husband and wife, and \$24.00 for a family.

Blue Shield plans should and will be expanded, as rapidly as can be safely done through the gathering of actuarial experience, to include medical care and a wider range of incomes by the grading of fees.

Having seen how desirable it is to use prepayment plans for the more costly and financially crippling hospital illnesses, people are now demanding similar protection against all medical care and all sickness. Here comes the rub, for there is a wide divergence of opinion concerning what this pro-

tection will cost, estimates varying all the way from \$26.00 to \$66.00 a year per person.

Ross-Loos Medical Group

The Ross-Loos Medical Group, of Los Angeles, a partnership of physicians, gives 27,000 persons complete medical care in homes and in the clinic and permits ninety days' hospitalization for \$30.00 a year. Obstetric and dental care and the care of venereal disease are not included. This group has had a stormy career, being opposed by the American Medical Association and suffering from financial growing pains because its actuarial figures were at first faulty.

Kaiser Permanente Foundation

The Permanente Foundation, of Henry Kaiser, an industrial-insurance plan that provides medical care in the company hospital at \$6.00 a year for 62,000 employees, has recently attracted attention. The foundation plans to take families of three or more for \$7.50 a month, — \$90.00 a year, — or \$30.00 per person, which is a reasonable sum for complete medical care.

The Group Health Association

The Group Health Association, in Washington, D. C., has also been much in evidence because of the suit brought by the United States Government against the American Medical Association.

Compulsory Insurance

Comprehensive compulsory health insurance by governmental legislation was first advanced as far back as 1916. The Workmen's Compensation Act resulted, but interest in health insurance lapsed and was not resumed until 1932, when the Social Security Bill was proposed. The medical plans therein set forth were pigeonholed, but the old-age pension and unemployment features of the bill were enacted. Ever since that time the health-insurance proposals have been revived from time to time, and these have recently been given prominence by the introduction of the Wagner-Murray-Dingell Bill. The American Medical Association has opposed all such legislation. Scrutiny of this bill has revealed many defects. Many groups have studied it, and some have made helpful suggestions concerning how such legislation can be safeguarded.

The recommendations made by a group known as the Health Program Conference are the most complete and rational of those proposed. They were published as "The Principles of a Nationwide Health Program" in November, 1944, by the Committee on Research in Medical Economics of New York, a foundation-supported organization. This program is too long to describe in detail, but its ten principles give some idea of its character. These are as follows: comprehensive coverage and service, spreading of costs, distribution of facilities according to community health requirements, encouragement of group medical practice, with hospital and

professional health centers, determination of policy through the participation of those who receive and of those who furnish service, responsibility of the medical profession for strictly medical activities, freedom of choice for physicians and patients, adequate payment of physicians and hospitals by methods that encourage quality and promote economy of service, a national system, and local administration of services under national standards.

Certain points deserve emphasis. A national system has obvious advantages. One of these is collection of payment through wage deductions, which gives benefits regardless of place of residence. Local administration is necessary because federal administration cannot adjust itself to local conditions, and because decentralization is mandatory. Control of policy should be in the hands of physicians and subscribers, not in those of a government bureau head such as the Surgeon General of the United States Public Health Service. Distinction between administrative and medical responsibilities is required, for physicians must be charged with the latter only.

The costs are to be met by contributions amounting to 12 per cent of all wages up to \$3000 a year, 6 per cent to be paid by employers and 6 per cent by employees. This means that a worker earning \$2000 will have to pay \$120. For this sum he and his dependents will receive full medical care in the home, the doctor's office and the hospital.

* * *

The proposals for health insurance comprise three views, supported by as many different groups.

The American Medical Association opposes any national legislation, insists on individualism and advocates the extension of Blue Shield and Blue Cross plans.

The American Hospital Association proposes grants-in-aid to the states for all necessary hospital and medical care for recipients of public assistance, which strikes at the heart of an important economic problem of sickness, and the promotion of Blue Cross plans. Health and health service, it is held, are extremely personal matters. The best results are obtained when patients co-operate actively in a program of prevention and treatment that includes the payment of costs. When such participation is voluntary, a certain amount of discipline of the worker, the hospital and the doctor is involved. This condition would not exist to the same extent under a taxation plan. The Blue Cross is essentially a form of public service, yet it accomplishes its aim without public compulsion. Federal employees cannot authorize deductions for the Blue Cross. It would be well for the Government to allow this. The American Hospital Association also favors grants to states for the erection of hospitals where needed when the community cannot afford to provide them, extension and expansion of Blue Shield activities

and the development of group medicine in clinics and hospitals.

The proponents of compulsory plans hold that, even granted that voluntary plans are growing, they are too slow and will never include all those who should be protected, that there will be wide differences in coverage and benefits and that a voluntary system is spotty and not inclusive. These persons believe that it will be a simple matter to extend the mechanism of the present Social Security Act to include comprehensive medical care for all wage earners throughout the country, but that this can be successfully accomplished only through compulsory legislation.

The following defects of compulsory insurance have been pointed out. People dislike compulsion. They also dislike federal control. (This can be partially overcome by decentralization through the local administration of distribution of benefits.) They fear bureaucratic development and control of doctors and hospitals and dictation as to medical care. They fear political intrusion. Lastly, they are perturbed by the increasing number of pay deductions for taxes. This plan will immediately increase these by 6 per cent, and ultimately each wage earner will pay 4 per cent more, a total of 10 per cent, which will bring the total tax payment to 35 to 40 per cent.

The present situation reduces itself to the question whether people wish to have insurance against sickness develop gradually through the extension and development of voluntary plans, such as those of the Blue Cross and the Blue Shield, which they can join if they so desire, or prefer to have federal legislation that will set up a comprehensive compulsory health-insurance plan covering all wage earners, with eventual payroll deductions of 10 per cent. The chief advantage of the first method is that, although slow, it is evolutionary and voluntary, that of the second method is that it will be immediate and comprehensive. The main disadvantage of the compulsory method is that it cannot help being cumbersome, with the inherent faults of bureaucratic control and, ultimately if not immediately, the intrusion of politics.

The object of the present lecture is not to settle this question, but to present the facts of the situation for study and evaluation.

Society and selected representatives of industries whose employees are insured

It is preferable to insure under the group method, since thereby no physical examination is necessary because the undesirable risks are automatically cancelled. Sixty per cent of the employees of any group of 50 or more must be enrolled, below this number a higher percentage must participate. Individual subscribers can be enrolled by submitting to a physical examination, for which they pay. The cost of membership is \$10.00 a year for single persons, \$19.80 for a husband and wife and \$24.00 for a family, regardless of the number of children.

The Blue Cross collects money from its subscribers, issues certificates of membership, makes contracts with hospitals and pays the hospital charges of its members. The hospital makes to the Blue Cross exactly the same charges, with a few exceptions, that it would render to an ordinary patient, but with a maximum daily charge of \$6 for thirty days. As previously stated, if hospitalization is continued beyond this period, the Blue Cross pays 50 per cent of the hospital charges for ninety additional days.

Blue Cross plans are quite satisfactory so far as hospitalization goes, since they are inclusive, economical and widely available.

The Blue Shield

The success of hospital-insurance plans has led to a demand for similar insurance to cover professional fees for hospital illnesses. To meet this demand, organizations have been set up and sponsored by state and other medical groups. They were started later than the Blue Cross but are now operating in thirteen states, containing 50 per cent of the population of the United States. The largest unit is in Michigan.

The Blue Shield, the name applied to the corporation founded by the Massachusetts Medical Society, was formed in June, 1943. It insures single persons with annual incomes up to \$2000 and families with incomes up to \$2500 and pays their doctors' fees for surgical or obstetric care in hospitals. The doctors participating in this plan accept a standard fee for operations and obstetric care. About 88,000 persons are now enrolled. The cost of membership is \$10.00 a year for single persons, \$19.80 for a husband and wife, and \$24.00 for a family.

Blue Shield plans should and will be expanded, as rapidly as can be safely done through the gathering of actuarial experience, to include medical care and a wider range of incomes by the grading of fees.

Having seen how desirable it is to use prepayment plans for the more costly and financially crippling hospital illnesses, people are now demanding similar protection against all medical care and all sickness. Here comes the rub, for there is a wide divergence of opinion concerning what this pro-

tection will cost, estimates varying all the way from \$26.00 to \$66.00 a year per person.

Ross-Loos Medical Group

The Ross-Loos Medical Group, of Los Angeles, a partnership of physicians, gives 27,000 persons complete medical care in homes and in the clinic and permits ninety days' hospitalization for \$30.00 a year. Obstetric and dental care and the care of venereal disease are not included. This group has had a stormy career, being opposed by the American Medical Association and suffering from financial growing pains because its actuarial figures were at first faulty.

Kaiser Permanente Foundation

The Permanente Foundation, of Henry Kaiser, an industrial-insurance plan that provides medical care in the company hospital at \$6.00 a year for 62,000 employees, has recently attracted attention. The foundation plans to take families of three or more for \$7.50 a month, — \$90.00 a year, — or \$30.00 per person, which is a reasonable sum for complete medical care.

The Group Health Association

The Group Health Association, in Washington, D. C., has also been much in evidence because of the suit brought by the United States Government against the American Medical Association.

Compulsory Insurance

Comprehensive compulsory health insurance by governmental legislation was first advanced as far back as 1916. The Workmen's Compensation Act resulted, but interest in health insurance lapsed and was not resumed until 1932, when the Social Security Bill was proposed. The medical plans therein set forth were pigeonholed, but the old-age pension and unemployment features of the bill were enacted. Ever since that time the health-insurance proposals have been revived from time to time, and these have recently been given prominence by the introduction of the Wagner-Murray-Dingell Bill. The American Medical Association has opposed all such legislation. Scrutiny of this bill has revealed many defects. Many groups have studied it, and some have made helpful suggestions concerning how such legislation can be safeguarded.

The recommendations made by a group known as the Health Program Conference are the most complete and rational of those proposed. They were published as "The Principles of a Nationwide Health Program" in November, 1944, by the Committee on Research in Medical Economics of New York, a foundation-supported organization. This program is too long to describe in detail, but its ten principles give some idea of its character. These are as follows: comprehensive coverage and service, spreading of costs, distribution of facilities according to community health requirements, encouragement of group medical practice, with hospital and

was given intramuscularly every two hours. The nonprotein nitrogen rose to 160 mg per 100 cc. Large hemorrhagic patches and purpuric spots appeared over the entire body. Respiratory distress became pronounced, with hemoptysis. Rales were heard in both lungs. The pulse became slow, and the respirations more difficult. The patient expired one month after admission.

DIFFERENTIAL DIAGNOSIS

DR. CHARLES L. SHORT: In summary, this is a patient with a definite past history of treated syphilis, and a positive Hinton test eight years before entry. These facts immediately introduce a disturbing element, but one that I am willing to eliminate as a primary factor in the terminal illness, provided that syphilis is not the etiology of the cardiac murmurs and valvular disease. The quality of the murmurs is not described but evidently there was a loud systolic murmur as well as a diastolic murmur at the aortic area, which was transmitted to the neck. We should like to know whether there was a thrill and whether aortic stenosis might have been diagnosed, thus suggesting rheumatic heart disease.

Perhaps the x-ray films will show whether there was dilatation of the aorta.

DR. CLAYTON H. HALE: The aorta is not remarkable in this film. It does not appear widened but there is slight tortuosity. The heart itself is only slightly enlarged, without characteristic configuration. This plain abdominal film shows the large spleen and the calcified nodes.

DR. SHORT: Can you see the liver?

DR. HALE: The liver edge does not show up particularly well. There is only slight if any enlargement of the liver, however.

DR. SHORT: A lot of skeletal films were taken. I suppose that we can assume that they were negative.

DR. HALE: That is correct.

DR. SHORT: And the calcified area is probably due to old tuberculous lymph nodes?

DR. HALE: I should think so.

DR. SHORT: The aortic lesion was probably nonsyphilitic. This is also favored by the negative Hinton test at the time of admission and the lack of preceding symptoms suggesting syphilitic aortitis. The skeletal x-ray films were probably taken with a view to the diagnosis of multiple myeloma, although, of course, they might have been taken with any form of malignant disease, probably metastatic, in mind. The diagnosis of multiple myeloma is a possibility, but the negative x-ray films, the lack of Bence-Jones proteinuria, the low serum protein and the absence of anything suggesting bone pain until late in the disease make it unlikely.

To go on with the summary, the patient had indefinite constitutional symptoms five months before the purpuric spots appeared. He contracted what

was probably an intercurrent upper respiratory infection, and this may have been a precipitating factor in the severe epistaxis that brought him to the hospital. On examination he had the murmurs I have mentioned, purpuric spots and a few somewhat enlarged lymph nodes, one of which was biopsied and found to show only chronic inflammation. He had a palpable, possibly enlarged liver and an enlarged spleen. In addition, he had a fever of 102°F. On the laboratory side he had a moderate normochromic anemia and a low white-cell count, with the neutrophils showing a shift to the left, suggesting infection. He had normal renal function as measured by the urinary findings and the nonprotein nitrogen. Studies regarding the purpura disclosed no significant increase in the prothrombin time, an increased bleeding time and a definitely increased clotting time.

The x-ray films that we have seen are not helpful. The patient had a downhill course, with chills and a spiking fever to 103°F, the development of ascites and finally either cardiac failure or bronchopneumonia, or perhaps both. He continued to bleed and he had a terminal rise in the nonprotein nitrogen without any mention of what the urinary findings were at that time.

On reading this case over rapidly my first impression, which is sometimes but not always the best one, was that he had severe liver disease, presumably cirrhosis. The bleeding, although the prothrombin time was not definitely increased, the low white-cell count, the depressed serum albumin, the ascites, the palpable liver and the splenomegaly all seem to fit in with this diagnosis. After reading more carefully, however, I found the sentence stating that he had a fever of 103°F, with chills. This made me pause, as well as the absence of jaundice in a patient with as much bleeding and who was as sick as this. I believe, and Dr. Jones may correct me on this, that a fever of this type and duration is incompatible with the diagnosis of hepatic cirrhosis in the absence of a complicating infection. I accordingly decided against that diagnosis.

The primary or idiopathic form of purpura must, of course, be considered. As for the thrombopenic variety, the bleeding time was only slightly, if at all, increased compared to the clotting time. The clot retraction was presumably normal, and the platelets were said to be decreased, rather than absent or nearly absent. In regard to the type of idiopathic purpura that is not associated with platelet depression, cases as severe as this have been described with fatal termination, but the diagnosis is questionable. Probably many of them were cases of disseminated lupus erythematosus. And this brings up the possibility of disseminated lupus, which may be associated with severe purpura, in addition, I remember one patient who also had ascites. I do not believe, however, that there is enough positive evidence to consider that diagnosis any further.

CASE 32031

PRESENTATION OF CASE

A fifty-one-year-old man entered the hospital complaining of severe nosebleed.

Six months before admission he first noted undue fatigability, anorexia and malaise. These symptoms increased during the following months. He was forced to quit his occupation of messenger and did a number of odd jobs, including painting. One month before admission, numerous small, red, non-elevated, nonitching, painless spots appeared over the lower legs and feet. An individual spot would persist for a time and disappear. New lesions would then develop. Three weeks before admission he was exposed to rain and cold and contracted a severe cold. His nose was obstructed, and a dry hacking cough developed. Each morning he awoke with a severe frontal headache, relieved by clearing the nasal passages. The material produced on blowing the nose resembled clots of blood, but there was no actual bleeding. He had had cramping pains in the calves and thighs, relieved by exercise. The evening before admission severe hemorrhage occurred from the right nostril and lasted for six hours. There was no bleeding from the gums. During the previous six months he had lost 16 pounds of weight.

There was no history of rheumatic or scarlet fever. Twenty-five years before admission he had been treated at this hospital for syphilis over a period of three years. Eight years before admission, the blood Hinton test was positive.

Physical examination revealed the patient to be well developed and thin, he appeared fatigued and uncomfortable. The pupils were normal. There was no epistaxis. The skin was extremely dry, with scaling over the lateral aspect of the right leg. One posterior cervical node was palpable, and one in the right axilla. A Grade III systolic and a diastolic murmur were heard over the aortic area and were transmitted upward along the great vessels. A Grade II systolic murmur was heard at the apex. The lungs were clear except for inspiratory rales at the right base. The liver was palpable three finger-breadths below the right costal margin and was

firm and nontender. The spleen was firm, nontender and palpable 6 cm. below the left costal margin, 1 cm. to the left of the midline. There were numerous purpuric spots, measuring 1 to 3 mm. in diameter, over both legs up to the groin. A tourniquet test was positive.

The temperature was 102°F, the pulse 90, and the respirations 30. The blood pressure was 130 systolic, 70 diastolic.

The red-cell count was 3,700,000, with 10.5 gm. of hemoglobin. The white-cell count was 4600, with 70 per cent neutrophils, 18 per cent of which were immature. The platelets were decreased. The bleeding time was 4½ minutes, and the clotting time 45 minutes. The urine was cloudy, amber and acid, with a specific gravity of 1.022. It contained no albumin, casts or cells. The nonprotein nitrogen was 30 mg. per 100 cc. and the total serum protein 4.8 gm., with 2.8 gm. of albumin and 2.0 gm. of globulin. The prothrombin time was 21 seconds (normal, 15 to 18 seconds). The serum chloride was 98 milliequiv. per liter. A blood Hinton test was negative. Four blood cultures were negative.

An x-ray film of the chest revealed clear lung fields and a normal-sized heart. The spleen was enlarged. There were no abnormal soft masses in the abdomen. There were several calcified areas in the right upper quadrant. The skull, lumbar spine, pelvis, humeri and knees were negative.

The white-cell count varied from 2400 soon after admission to 12,600 later in the course of his disease. The temperature spiked from 99 to 103°F, with chills.

Nine days after admission the patient complained of sharp pain in the lumbar region, more marked on the right than on the left, which was aggravated by motion. Slight tenderness was elicited over the right costovertebral angle, but according to the patient the pain was more medial. X-ray examination showed no fractured rib. The abdomen was not tense, but distended with gas and tympanic. Evidence of free fluid was present. Peristalsis was high pitched. A flat film of the abdomen revealed a considerable amount of gas in the colon and less in the lower loops of the small intestine. Repeated blood and plasma transfusions resulted in an elevation of the plasma protein to 6.4 gm. Two days later more petechiae were noted over the legs. Biopsy of an axillary lymph node revealed chronic inflammation. The ascites increased. Paracentesis yielded 2500 cc. of slightly bloody fluid, with a specific gravity of 1.008. It contained 3 lymphocytes per cubic millimeter, but no bacteria or tumor cells were seen on smear. The patient was much relieved by the procedure, but the fluid again rapidly accumulated. Gaseous distention and lumbar pain persisted. Paroxysmal sinus tachycardia appeared and the patient became dyspneic. He coughed up thick pinkish-white sputum. Shifting dullness was found in the right chest. Penicillin (32,000 units)

ndocarditis In this picture (Fig 1) you can see the interadherence of the two cusps at the commissure. There, also, the part of the cusp not involved with bacterial endocarditis is thickened, showing the old rheumatic infection You can also see the thickening of the chordae tendineae of the aortic leaflet of the mitral valve The chordae were slightly shortened, but not enough to cause appreciable stenosis Microscopically there were small infarcts in the myocardium due to small emboli from the aortic valve These may be a real factor in the production of the cardiac failure seen in subacute

DR JONES We have seen it, but the cirrhosis is usually accompanied by real liver failure I wonder whether there was much hepatic failure

DR CASTLEMAN There may have been a little, but microscopically there was only mild cirrhosis and slight chronic passive congestion

DR RICHARDSON What about the increased clotting time? Can you answer that? He certainly had an increased clotting time and a tendency to bleed, and they were not due to platelet lack

DR CASTLEMAN Patients with bacterial endocarditis do have a tendency to bleed I am under

FIGURE 1 Photograph of Heart

bacterial endocarditis This man also had infarcts in both kidneys, and I suppose the pain in the back was due to one of these infarcts The spleen weighed over 400 gm and showed infarction There was a severe terminal bronchopneumonia He had a mild portal cirrhosis, which may or may not have had anything to do with the recent illness

DR RICHARDSON Why the ascites? Was it cardiac? Since he had a low protein, I should think that one could say that the liver did have something to do with it

DR CASTLEMAN It was a very mild cirrhosis, with only slight fibrosis in the portal spaces The liver had not shrunk, in fact it was larger than normal I had supposed that the anasarca was due to cardiac failure It could have been due to a combination of both factors

DR RICHARDSON The serum protein was certainly low

DR CASTLEMAN Yes, but I do not recall having seen 2 liters of fluid in each pleural cavity as a result of a low protein

the impression that some of the so-called "petechiae" seen in subacute bacterial endocarditis are not embolic but the result of capillary damage

DR BLAND That is one idea, but I have never seen it happen in the presence of such an increase of the clotting time

DR SHORT I have never heard of a case like this, with a bleeding tendency associated with an increased clotting time

DR RICHARDSON It is usually due to a toxic purpura

DR BLAND This is a disturbing case. I have looked for years for a case with this degree of heart failure and a normal-sized heart I think that other factors should be emphasized Were the veins distended?

DR COTZIAS Dr Kennedy thought that they were not distended

DR BLAND That is against heart failure

DR JONES Perhaps the anasarca was due to a low serum albumin without cirrhosis A number of cases get a low albumin due to prolonged malnutrition

In any obscure illness periarteritis nodosa sooner or later raises its head, and it must be thought of here. Purpura has been described in this disease, but again there are no characteristic manifestations to allow me to discuss this possibility further.

One must also mention lymphoma in passing, which was evidently considered, on account of the lymph-node biopsy. I think we can also pass by lymphoma, as well as leukemia, with the comment that positive evidence is wanting.

So far I have not mentioned any disease of known infectious origin except syphilis. Those in charge of this patient evidently thought of this possibility when the blood cultures were taken and when they finally began to treat him with penicillin. I think that a diagnosis of subacute bacterial endocarditis must have occurred to all of you, with the combination of a valvular lesion, chills, fever, anemia and an enlarged spleen. I say "a valvular lesion," although that has not been proved, but I think that we must assume that it was there and that the murmurs were not merely associated with a moderate anemia, which he had on admission to the hospital. Frank purpura with platelet depression is occasionally found in this disease. The outs about this diagnosis are the negative blood cultures, which do not eliminate it, and the development of ascites, although the latter may have been due to cardiac failure or the low serum albumin, or to a combination of the two. The lumbar pain may be explained on the basis of renal infarcts. These or likelier the glomerulonephritis found quite often in cases of subacute bacterial endocarditis may have accounted for the terminal rise in nonprotein nitrogen. So I should like to propose as a diagnosis in this case subacute bacterial endocarditis arising from rheumatic disease of the aortic valve.

DR BENJAMIN CASTLEMAN Dr Bland, have you an opinion?

DR EDWARD F BLAND I agree with Dr Short.

DR WYMAN RICHARDSON This was indeed a puzzling case. I should like to say that, so far as the murmurs were concerned, Dr Kennedy of the House Staff in one of the later notes stated that a definite mitral murmur was heard, which led to the diagnosis of a rheumatic heart. I also put down a note saying that I could not hear this murmur. You can believe either one of us.

Another puzzling thing to me was the clotting time. It was definitely prolonged, and the tendency to bleed was not due to platelet lack. Was the sedimentation rate determined?

DR GEORGE C COTZIAS Yes, it was increased.

DR RICHARDSON If the increased clotting time was due to severe liver disease and fibrinogen lack, the sedimentation rate might have been slow, but I do not know whether that can be used as a yardstick. We did not measure the actual fibrinogen levels in the blood, which might have been interesting.

I wrote in the record as follows:

I cannot easily put this picture together. There is not sufficient evidence in the blood picture to establish a diagnosis of leukemia. The platelets, although reduced, are not low enough to produce purpura, the bleeding time is normal. He has a "toxic" purpura, possibly enhanced by prothrombin lack. The heart lesion, which I think is aortic regurgitation without definite mitral stenosis, as well as syphilitic. However, I think the most likely diagnosis is bacterial endocarditis, with superimposed liver failure, probably cirrhosis.

DR CHESTER M JONES Dr. Short raised the question of fever in relation to cirrhosis. Occasionally in cirrhosis one gets prolonged fever, usually individual spikes for two or three days. It could go to that height or higher in short spikes.

DR SHORT But not a continued fever and not with chills?

DR JONES No, continuous fever is unusual. In regard to the sedimentation rate, I think that Dr Richardson is wrong. In cirrhosis of any degree the sedimentation rate is usually greatly increased. One thing against an early type of cirrhosis is the one figure for the globulin, which was relatively low. Most advanced cases of cirrhosis tend to have normal or high globulin levels.

CLINICAL DIAGNOSES

Subacute bacterial endocarditis?
Purpura (? etiology)
Cirrhosis of liver?

DR SHORT'S DIAGNOSES

Subacute bacterial endocarditis
Rheumatic valvular disease, aortic, with regurgitation
Renal infarcts?
Glomerulonephritis?

ANATOMICAL DIAGNOSES

Subacute bacterial endocarditis, aortic valve
Rheumatic heart disease, with mitral and aortic involvement
Myocardial infarcts, small, multiple
Portal cirrhosis of liver, mild
Anasarca
Infarcts of kidneys and spleen
Bronchopneumonia

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN The autopsy showed what at first glance seemed to be severe cardiac failure. There was anasarca, with 3 or 4 liters of fluid in the abdominal cavity and 2 liters in each chest cavity, as well as peripheral edema. The heart, however, was normal in size and was involved with subacute bacterial endocarditis. There was old rheumatic heart disease, with mild involvement of the mitral valve and mild interadherence of the aortic cusps, but apparently not enough to produce cardiac hypertrophy. Superimposed on the old rheumatic aortic valve was a subacute bacterial

the spine. Six weeks before readmission, the patient noticed pain in the lower anterior portion of the left chest. It was constant, sharp and localized, and was made worse by lying down or on deep breathing. Three days before admission the pain became more severe than usual, and he had shaking chills.

On physical examination the left lower portion of the chest was dull to percussion laterally and posteriorly, with absent tactile fremitus and faint breath sounds.

The temperature was 101°F, the pulse 90, and the respirations 25.

The white-cell count was 6100, with 63 per cent neutrophils. The urine was negative. The non-protein nitrogen was 22 mg per 100 cc, and the serum protein 7.2 gm, with 4.6 gm of albumin and 2.6 gm of globulin. The serum calcium was 8.6 mg per 100 cc, the phosphorus 2.5 mg, the alkaline phosphatase 11.7 Bodansky units, and the acid phosphatase 1.2 units. The urinary calcium output was 158 mg in twenty-four hours.

An x-ray film of the chest showed that the left lower lung field was obscured by ground-glass density. There was a linear area of increased density along the left lateral chest wall. The right lung field was clear. After thoracentesis had been done, it was found that the lung markings of the left lower lobe were crowded behind the heart. The visualized bones of the dorsolumbar spine and pelvis showed no definite evidence of metastatic involvement.

One month later only a small amount of fluid was found in the left pleural cavity, chiefly posteriorly, obliterating the left costophrenic sinus. The left lower lobe was markedly decreased in size. There was slight displacement of the heart and mediastinum to the left, and considerable emphysema of the left upper lung field. The heart and the right lung were normal. Two months after admission, narrowing of the interspace between the twelfth dorsal and first lumbar vertebrae was seen. The first lumbar vertebra showed multiple areas of diminished density throughout, particularly in the anterior portion of the body. About these areas of diminished density were areas of increased density. The skull, lower legs, forearms and hands showed no bony abnormality.

Repeated thoracenteses were done, which yielded up to 1000 cc of dark-yellow, slightly hazy fluid that contained no acid-fast bacilli or tumor cells. The patient continued to complain of lumbar pain, and also of abdominal pain radiating to the flank, with tenderness. Bronchoscopy was negative. He was discharged somewhat improved.

Sixth admission (three months later). The pain in the lower back, hips and legs had continued, being severer on the right than on the left. There were areas of numbness on the anterior and lateral aspects of each thigh. There was no pain in the neck.

Physical examination revealed dullness to percussion over the left lung base in an area about 6 cm

wide. The breath sounds were normal. There was slight tenderness over both costovertebral angles. The left knee jerk was less active than the right. The abdominal reflex was questionably absent on the right. Over the areas of subjective numbness described above, the patient was unable to distinguish between sharp and dull.

The white-cell count was 7700, with 69 per cent neutrophils. The urine was negative. The serum calcium was 11 mg per 100 cc, the phosphorus 2.4 mg, the alkaline phosphatase 8.7 Bodansky units, and the acid phosphatase 2.4 units. A guinea pig inoculated with chest fluid obtained three months previously was killed and reported to be negative. Agglutination tests for typhoid fever and brucellosis were negative.

An x-ray film of the chest revealed no change in the appearance of the lungs. The destructive process involving the bodies of the twelfth dorsal and first lumbar vertebrae had increased, with narrowing of the disk space. At the lower portion of the body of the twelfth thoracic vertebra there was a cavity apparently containing sequestrums. There was also beginning involvement of the lower surface of the first lumbar vertebra and the disk below it.

Lumbar puncture obtained clear fluid under an initial pressure equivalent to 105 mm of water. On jugular compression the pressure rose to 350 mm and fell slowly to 130 mm in release, the final pressure was 90 mm. The total spinal-fluid protein was 47 mg per 100 cc.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR OTTO E. AUFRANC. It seems that, chemically, this patient improved considerably after the adenoma of the parathyroid gland was removed. So we might eliminate that entirely from the discussion.

May we see the x-ray films?

DR CLAYTON H. HALE. This chest film shows evidence of old pleurisy on the left, and the left lower lobe is collapsed. No evidence of metastases is seen, and there is no definite tuberculous lesion in the lung fields. This film of the abdomen was part of an intravenous pyelogram and shows normal kidneys. There are hypertrophic spurs of the vertebral bodies, most marked about the second lumbar vertebra. The next films, taken in the early part of this year, show definite destruction of the twelfth thoracic vertebra, and there also appears to be narrowing of the twelfth interspace. I cannot make out a definite soft-tissue mass about this vertebra, although the psoas shadow on the right in some of the films looks a little fuller than that on the left. In the differential diagnosis one must consider a malignant neoplasm, primary or metastatic, and infection. The fact that the interspace is narrowed suggests an infectious process, even though we do not have a definite soft-tissue mass to go with it.

DR. SHORT Did he have glomerulonephritis?
 DR. CASTLEMAN No

CASE 32032

PRESENTATION OF CASE

First admission A forty-one-year-old man, a foundry chipper by trade, entered the hospital complaining of pain about the umbilicus, radiating to the right lower quadrant and to the right testis.

Fifteen years before admission the patient had had severe right renal colic and had passed a stone. Following this attack, he had had many other episodes of renal colic, passing stones each time.

Physical examination was negative.

The red-cell count was 4,100,000, with 75 per cent hemoglobin. The white-cell count was 9100. The urine was light amber and acid, with a specific gravity of 1.020. It gave a + test for albumin, and the sediment contained 150 red cells and an occasional white cell per high-power field. The urine was sterile on culture. The nonprotein nitrogen was 23 mg per 100 cc, and the serum protein 6.1 gm. The maximum serum calcium was 15.7 mg per 100 cc, with a phosphorus of 2.4 mg. The alkaline phosphatase was 10.7 Bodansky units. The urinary calcium output was 489 mg in twenty-four hours. A blood Hinton test was negative.

An x-ray film of the abdomen showed a 1-cm stone in the region of the right kidney pelvis. There were two minute areas of calcification in the lower pole of the left kidney. The bones were normal in density.

The patient underwent a right pyelolithotomy, from which he recovered uneventfully. The stone obtained consisted of phosphatase.

Second admission (one month later) The patient was readmitted to the hospital, and an adenoma of the left lower parathyroid gland, measuring 2 by 1.5 by 1.5 cm, was removed. The patient recovered without tetany. Two days after the operation, the serum calcium was 10.3 mg per 100 cc, the phosphorus 1.5 mg, and the alkaline phosphatase 7.1 Bodansky units. The Sulkowitch test for urinary calcium was negative at discharge.

Third admission (twenty months later) After discharge the patient felt well and passed no stones. Soon, however, he noted the gradual development of an area of hypesthesia on the anterior aspect of each thigh. Each area was small at first but then grew larger, involving the lateral aspect of the thigh as well. Five months before readmission he had a chill, and a short time later he complained of a dull, constant, nonradiating ache in the midline of the upper lumbar region, which was associated with a considerable amount of spasm of the lumbar muscles. Exertion seemed to relieve the pain somewhat, and leaning forward and to the right aggravated it. An x-ray film showed moderate scoliosis of the dorsal spine, with convexity to the right. The

lumbar spine had a mild compensatory scoliosis to the opposite side. The neural arches of the first sacral segments were not united. There were hypertrophic changes throughout the spine. Two fairly large spurs arose from the lateral margins of the body of the second lumbar vertebra. In spite of a back brace and a change to a lighter type of work, the back pain persisted, occasionally waking the patient at night. It became much worse on coughing or sneezing. The patellar and Achilles tendon reflexes were diminished. There was no Babinski sign. Since the pain had become so severe, he was admitted for further study.

There was no tenderness of the lumbar vertebrae at the site of the pain, which was especially severe when the patient straightened up after leaning over.

The serum calcium was 9.6 mg per 100 cc, the phosphorus 2.4 mg, and the alkaline phosphatase 6.8 Bodansky units. The spinal fluid was negative.

An intravenous pyelogram was negative. The bones of the lumbar spine and pelvis were slightly decalcified, and there was incomplete fusion of the laminae of the sacral segments. There were moderate degenerative changes about the bodies of the first and second lumbar vertebrae. A lateral film of the lumbar spine and stereo films of the sacroiliac joints revealed normal intervertebral-disk spaces. There was slight new-bone formation in the antero-central portion of the left sacroiliac joint. A gastrointestinal series and a barium enema were negative.

The pain persisted, with variations in intensity. The hypesthesia of the thighs also continued. Several weeks after admission the patient began to expectorate about 10 cc of blood-tinged fluid every morning. There was no cough. No bleeding point was found in the mouth or pharynx. A chest film showed normal lungs. On discharge, two months after admission, he was walking for short periods and complained infrequently of slight back pain.

Fourth admission (one year later) Three weeks after discharge the patient returned to the Out Patient Department, with marked increase in the back pain. X-ray treatment (600 r) was given over the lower lumbar vertebrae and sacrum, with no relief of pain. Two days before readmission, after several hours of malaise, the patient noticed pain in the right lower quadrant of the abdomen. There had been no nausea or vomiting.

Tenderness, voluntary spasm and rebound pain were elicited in the right lower quadrant. The white-cell count was 8800.

A laparotomy was done, and an acutely inflamed appendix was removed. Convalescence was uneventful.

Fifth admission (four months later) Several weeks after operation, the pain became much worse, with radiation in a band-like manner around the anterior abdominal wall. There was considerable spasm of the sacrospinalis musculature, with limitation of flexion, extension and lateral bending of

SUBSCRIPTION TERMS: \$6.00 per year in advance, postage paid for the United States (medical students \$3.50 per year); Canada \$7.04 per year (Boston funds); \$8.52 per year for all foreign countries belonging to the Postal Union.

MATERIAL should be received not later than noon on Thursday, two weeks before date of publication.

THE JOURNAL does not hold itself responsible for statements made by any contributor.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts.

program appears elsewhere in this issue of the *Journal*. That an unusual opportunity for postgraduate instruction will be provided is evidenced by those who have signified their willingness to serve as chairmen. All who take part in the program are generously donating their time.

Although this series of lectures is primarily intended for the general practitioners and returned medical officers of Greater Boston, any licensed physician may enroll, and is urged to do so, there is no registration fee. All who plan to attend should enroll either by mailing the return postcard that has already been sent to all physicians in Massachusetts or by communicating directly with the Committee on Postgraduate Medical Education, Massachusetts Medical Society, 8 Fenway, Boston 15.

CLINICAL INVESTIGATION BY THE VETERANS ADMINISTRATION

A PAPER published elsewhere in this issue of the *Journal* is a token of the vast amount of useful medical information in the records of the Veterans Administration that is ripe for harvesting if pains are taken in the cultivation of the field. The problems are numerous, and the numbers of disabled veterans are large in almost every category. Furthermore, there are already able and far-sighted physicians in the Veterans Administration who are anxious to utilize to the full the golden opportunity that now presents itself in the adequate follow-up study of the cases under their jurisdiction, both for the sake of the patients themselves and for the sake of new knowledge, which is certain to come if the study is well carried out.

In the cardiovascular field alone one can list five major problems that are in urgent need of concentrated follow-up study, which should be possible from the wealth of material under the care of the Veterans Administration: rheumatic fever and its effect on the heart, hypertension, early coronary heart disease, peripheral vascular diseases and neurocirculatory asthenia. Much could be learned from a detailed study of the patient under the age of forty years who is afflicted with angina pectoris or acute coronary occlusion, and this type of case

REFRESHER COURSE FOR PHYSICIANS

THE attention of all physicians in Massachusetts is called to the series of review lectures that has been arranged for the Greater Boston area by the Subcommittee on Postgraduate Medical Education of the Postwar Planning Committee of the Massachusetts Medical Society in co-operation with the Massachusetts Department of Public Health. In contrast to the method employed in the outlying districts, whereby a team of instructors gives an intensive course of talks at several localities in the district three or four times a year, this series will comprise four lectures of approximately forty-five minutes each on Mondays and Wednesdays, beginning February 18 and ending May 15. The tentative

DR AUFRANC We have a forty-one-year-old man who, over two years' observation, had more or less constant pain in the back. During that time x-ray studies gradually pointed out a lesion in the lumbar spine, which at the last examination consisted chiefly of destruction, with some production of bone in one film. The anterior portion of the body of the vertebra showed sequestration, so that the differential diagnosis seems to narrow down to a few things, the likeliest one of which is infection. The slow development of the destruction may well point to some malignant tumor, metastatic or primary, but the fact that he had had episodes of chills and fever seems to suggest an infectious process rather than a tumor. The radiation of pain around the thighs and to the anterior abdomen may well have been accounted for by slightly increasing abscess formation anteriorly around the bodies of the vertebrae involved.

One of the most frequent types of infection at this age is tuberculosis, and the fact that this man had sequestral formation fits in with that possibility. Other types of low-grade infection, such as staphylococcal infection, typhoid fever and brucellosis, should also be considered. The gradual spread of hypesthesia and numbness is further evidence pointing to a small slowly growing abscess somewhere. I believe that the dull pain on the right side may be attributed to the operation for kidney stone. Among the other less likely infections that one might think of is echinococcal cyst, a case of which I had not seen until I was in the Army, but now that I am out, I suppose that I should forget about it.

Among the types of tumor to be considered are primary carcinoma, metastatic cancer and possibly hemangioma. If it were hemangioma, it should have shown up earlier. There was no apparent source for metastatic disease: the gastrointestinal system was negative, and the prostate and the thyroid gland, which was explored once, were negative. So more than likely we can rule out tumor.

There is one other possibility, but it may have no bearing on the case, namely, that a small sponge was left in the wound at the time of the kidney operation and that it eventually resulted in a small abscess in the body of the vertebra, indicated by destruction around the body of the vertebra. I am not sure, however, that such an abscess would produce that much bone destruction.

My diagnosis is an infection — most probably not tuberculosis because of the slow rate of onset and the absence of tubercle bacilli, although I do not know that the latter rules it out. It was possibly osteomyelitis of the spine, with sequestral formation and a small abscess. There is no note concerning what was found at the time of appendectomy or whether the area was palpated, so there might have been a mass that was missed. The second possibility is tuberculosis.

DR MARIAN W ROPES This patient was a problem to us for two years. During the first part of the observation we hunted hard for a malignant tumor, since we thought that this was the likeliest explanation, but we failed to obtain any evidence other than the elevated phosphatase, which had persisted since the parathyroidectomy. The other two possibilities considered were rheumatoid spondylitis and tuberculous infection of the spine. Incidentally, the record does not describe the improvement that took place last winter, at which time he became almost symptom free and was able to work. At the time of this improvement I thought that rheumatoid spondylitis was probably the best explanation, but with the subsequent developments I thought that malignant disease or tuberculous infection were the two likeliest possibilities. The x-ray appearance never seemed quite satisfactory for either of these. The gradual development over the course of two years was surely surprising, particularly when there was no demonstrable x-ray change until the last few months.

DR CHARLES L SHORT I know the diagnosis, but I might say that, on seeing the patient after one of the operations, I thought that perhaps the pleurisy that he had had might have been considered in the differential diagnosis, in that way, perhaps on the basis of probability, the correct diagnosis might have been made.

DR RICHARDSON To me this case represents the value of a healthy amount of ignorance. I did not know enough to be puzzled very much. I said that this patient had a lesion of the bone, that he had had it for a long time and that he had also had recurring pleurisy with effusion, all of which to me meant tuberculosis. I advised against an operative procedure because I thought that if it were tuberculosis he might develop a sinus tract and difficulty in healing, I therefore suggested therapeutic doses of radiation. I did not realize that he had already been treated by x-ray.

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN At operation the surgeon encountered caseous tuberculosis, which was obvious even on gross examination. The slides confirmed that diagnosis. The fact that we were unable to recover tubercle bacilli from the pleural effusion does not rule out tuberculosis.

chemical mediation of nerve impulses, and in his last years to investigations "on the phenomena of a pace-maker in the rhythmic pulsations of the cerebral cortex"

Only World War I interrupted the continuity of his researches. The years 1917 and 1918 were spent in France and England, with a final rank of lieutenant colonel, and resulted in his brilliant studies on traumatic shock. These years were followed by an intense interest in world science and the freedom necessary for the cultivation of scientific pursuits. Since then he maintained that "a close relation exists between democracy and science" and "between liberty and democracy"

He acted on his convictions. He was the national chairman of the Medical Bureau to Aid Spanish Democracy, a member of the Joint Anti-Fascist Refugee Committee and the president of the American-Soviet Medical Society. Six months as visiting professor at Peking Union Medical College in 1935 led him later to become president of the American Bureau for Medical Aid to China and a director of the United China Relief organizations. He was foreign secretary of the National Academy of Sciences.

While a guest of the Russian Government, following his year in China, he had the courage to state his convictions regarding conditions essential for scientific progress in an address before the International Physiological Congress held in Moscow.

Another expressed conviction of Dr Cannon's was that "it is important for science to be understood in a democracy." Hence, among his books were four published for lay readers — three based on the results of his own and his collaborator's researches and one, his last, fortunately largely biographical, a description of the life of a scientist.

The broad application of Dr Cannon's investigations is indicated by his induction into membership in diverse special medical societies — the American Gastroenterological Association, the American Psychological Association, the American Psychopathological Association, the Association for the Study of Internal Secretions and the Société de Psychologie (Paris).

His travels, foreign lectureships, exchange professorships and attendance at medical meetings in all lands made Cannon the man as well as Cannon the scientist a truly international figure. In visits abroad, contacts that to most persons would have meant pleasant but temporary relations with Cannon resulted in permanent friendships. He had warm lifelong friends among distinguished scientists of many countries — Britain, France, Germany, Russia, Spain, Italy, the Argentine, Mexico and China. He had the broad sagacity of Benjamin Franklin and the democracy of Abraham Lincoln. His geniality, quick wit and delightful sense of humor enlivened any group he chanced to join and made him the best of companions on all occasions.

Every possible kind of scientific honor came to Dr Cannon — from this country, the Distinguished Service Medal, from England, Companion of the Bath, and from all civilized countries, memberships in learned societies and honorary degrees.

In the fall of 1931, Dr Cannon completed twenty-five years of service as George Higginson Professor of Physiology. The occasion was celebrated by the presentation of his portrait to the University and by afternoon and evening exercises at which the country's most distinguished physiologists and President Lowell spoke.

His achievements and honors did not change him. He remained always the approachable, honest, simple, devoted, modest gentleman, worthy of the pride of his university and his nation.

Who's Who contains a lengthy list of Dr Cannon's degrees, honors, decorations, honorary lectureships and societies, ten of his honorary degrees, however, are not mentioned, five of them from foreign universities. Also omitted are honorary memberships in fourteen foreign scientific societies and academies.

Dr Cannon realized more and greater satisfactions from life than come to most — in achievement, in the admiration and affection of his fellow-men and in his family. In spite of his many diversified activities related to his scientific and humanitarian activities, Dr Cannon was a devoted family man. He also found time to give to old friends and for the cultivation of new friendships. Regretful notices of Dr Cannon's death have come to the University from many lands.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

CAVANAUGH — Mortimer T. Cavanaugh, M.D., of Great Barrington, died October 7. He was in his seventy-fourth year.

Dr Cavanaugh received his degree from Baltimore Medical College in 1898. He was a fellow of the American Medical Association.

His widow survives.

GOODWIN — James J. Goodwin, M.D., of Clinton, died December 29. He was in his eighty-first year.

Dr Goodwin received his degree from the Jefferson Medical College of Philadelphia in 1892. He retired in 1943. He was a member of the American College of Surgeons and the New England Surgical Society.

His widow and three sons survive.

KAPLAN — Boris Kaplan, M.D., of New Bedford, died December 25. He was in his fifty-seventh year.

Dr Kaplan received his degree from Saratov Medical Institute, Russia, in 1918. He was a member of the National Gastroenterological Association and a fellow of the American Medical Association.

His widow and two children survive.

is already represented by hundreds of persons on the rolls of the Veterans Administration

Whatever is learned from such follow-up studies of the disabled veterans will be of immediate practical use in the diagnosis and treatment of the veterans themselves. It is not at all a matter of idle academic curiosity and experimentation. Hence, anything that can be done to foster the proper development of the medical work of the Veterans Administration will improve the care of the men and women who have helped so much in saving the world from tyranny, and will simultaneously advance medical knowledge. It is hoped that such a rare opportunity will not be allowed to slip, as it did after World War I.

OBITUARY

WALTER BRADFORD CANNON

1871-1945

Many generations of Dr. Cannon's forebears — on both sides — lived in America. Both lines were characterized by initiative and courage, and men and women among them were pioneers in the westward extension of American frontiers. Dr. Cannon was thoroughly and gloriously American.

In personality he was direct, absolutely genuine without tinge of artificiality, formal only when necessary to meet the amenities of special occasions. He met persons in all walks of life from the lowliest of employees to the world's most distinguished in science and administration, confidently, simply and directly, making real and sympathetic contact by virtue of his diversified experiences, his comprehensive intelligence and his love for all human beings. Competent in highest degree to appraise character and achievement, praise often came from him, condemnation rarely — and never expressed at large. One of the world's great scientists, he was for many years one of the most beloved and revered professors at the Harvard Medical School.

Dr. Cannon was born in Prairie du Chien, Wisconsin, on October 19, 1871. Much of his boyhood was spent in Wisconsin and Minnesota in essentially rural surroundings, whence came his resourcefulness in mechanics and interpretation of natural phenomena. Simple out-of-door pursuits — canoeing, walking and mountain climbing — and working with tools remained always his chief recreational activities. The whole of Dr. Cannon's adult life was spent as a student and faculty member at Harvard. In high school at St. Paul, Minnesota, and in Harvard College he was distinguished for high scholarship and extracurricular activities. In 1906, six years after graduation from Harvard Medical

School he was made George Higginson Professor of Physiology — a record in rapidity of appraisal by the medical school. Unusual too for that day was a young professor who had not been directly exposed to European influences. His early recognition by the University was understandable for he was already engaged in independently conceived research, the pursuit of which occupied him for the remaining forty years of his life and which, step by step, led him to become the world's outstanding investigator in the highest plane of physiologic research, that of the integration of many body systems in relation to the emotions.

His retirement in 1942 brought no interruption in research, only a move into the Biological Laboratories in Cambridge. For several months preceding his death, Dr. Cannon worked in Mexico City in order to collaborate with a favorite pupil, applying to research in neurophysiology of the brain information obtained from their researches on the peripheral systemic and sympathetic nervous systems.

A truly great school of physiology developed at Harvard because of Dr. Cannon's eminence as a scientist and because of those personal qualities that inspire respect and affection through inspirational guidance of pupils. More than forty persons holding professional or equivalent rank in important universities and institutions have been definitely exposed to Dr. Cannon's personal influence in their work. As a teacher of medical undergraduates he was a powerful influence and drew many talented men into his laboratories. He became the outstanding personality in physiology in this country and was one of the greatest figures in the Harvard Medical School in the period of its greatest progress.

Years ago, after carefully weighing his opportunities for service to the medical school, he declined the deanship. Always, however, his influence and services in the councils of the medical school were great. His judgment was always detached, his decisions prompt and productive of action. He was ever ready to fight in support of his convictions.

Dr. Cannon's first bit of research was done with Professor C. B. Davenport, while an undergraduate in college. In 1898, while a second-year medical student, he began his studies of the movements of the gastrointestinal tract by means of radio-opaque substances and x-rays. He soon discovered the great effect of the emotions on the gastrointestinal movements. Continued reflective thinking on the results of each set of experiments led to his studies on the sympathetic nervous system by itself and in co-operation with the glands of internal secretion. Most of the present-day knowledge regarding the physiologic significance of the sympathetic nervous system and its integration with the activities of ductless glands is the result of research completed by him and his collaborators before his sixtieth year. Subsequent, and to him obvious, lines of research led to his great contributions on the

The success of this treatment entirely depends on the efforts of the person using it. If the exercises are not performed regularly and often for a period of months, it is of little value. It takes time to build up the tone and strength of the facial muscles, as it does with any other group of muscles in the body.

I am submitting this idea not as a claim for the cure of one hut as a useful adjunct in its treatment.

NEIL C STEVENS

Walpole, New Hampshire

DERMATITIS FROM DDT SOLUTION

To the Editor: The public has waited impatiently for the much publicized DDT—dichloro-diphenyl-trichlorethane. Its use is, however, attended with a certain amount of risk, not so much because of the DDT itself but because of the solvents used in its preparation. The latter include crude kerosene, refined odorless kerosene, soy-bean oil, cyclohexylamine, xylene, acetone and ether. The most popular one is deodorized kerosene. This has not only the hazard of inflammability but also produces a dermatitis if it remains in contact with the skin for a sufficient length of time and under certain conditions, as shown by the following case report.

A fifty-two-year-old janitor presented a rash on the face, neck and back of hands of two weeks' duration. He showed erythema, fine vesicles and papules, the so-called "helmet type" of eruption frequently seen after exposure to irritating dust or fumes. History revealed that for several days shortly before the onset he had used as a spray a new preparation for killing insects. After each spraying episode his skin itched, until finally his face broke out in a rash. In the course of his occupation he also used floor wax. Investigation revealed that the spraying solution consisted of 5 per cent DDT, thiante and the bulk highly refined kerosene. He was given treatment and later patch tested with the following substances: the DDT solution, floor wax, pure powdered DDT, and a control. The last was prepared by applying the DDT solution to a cloth and allowing the solvent to evaporate before the cloth was applied to the skin. There was no reaction from the floor wax, pure powdered DDT or control, but there was a marked erythema and vesiculation at the site of the DDT solution, the erythema extending around the dressing for an area of over 2 cm. on either side.

Although DDT apparently does not cause a dermatitis, the solvents may and in spraying these solutions persons should exercise great care and protect the exposed areas of the skin.

JOHN G. DOWNING, M.D.

520 Commonwealth Avenue
Boston 15

NEW REGULATIONS OF DEPARTMENT OF MENTAL HEALTH

To the Editor: Under authority of Section 10 of Chapter 123 of the General Laws, the Department of Mental Health hereby establishes the entire state of Massachusetts, excepting the City of Boston, as the state-hospital district for children fifteen years of age or younger.

Commitments to Walter E. Fernald State School, Wrentham State School, Belchertown State School and Monson State Hospital will remain as before.

Effective January 1, 1946, no children fifteen years of age or younger are to be admitted to any of the following state hospitals: Boston, Danvers, Foxborough, Gardner, Grafton, Medfield, Northampton, Taunton, Westborough and Worcester.

Children fifteen years of age or younger from the City of Boston may be admitted to the Boston Psychopathic Hospital for short periods of study. Facilities for prolonged care of these children will be available only at the Metropolitan State Hospital, and if the need for prolonged care is anticipated, such children should be sent directly to the Metropolitan State Hospital. Boston committing courts may commit such children directly to the Metropolitan State Hospital without a waiver.

The intent of the new plan is to permit proper segregation of children from mentally ill adults and to provide adequate educational and recreational facilities for these children.

CLIFTON T. PERKINS, M.D., Commissioner
Department of Mental Health

100 Nashua Street
Boston

BOOKS RECEIVED

The receipt of the following books is acknowledged, and this listing must be regarded as a sufficient return for the courtesy of the sender. Books that appear to be of particular interest will be reviewed as space permits. Additional information in regard to all listed books will be gladly furnished on request.

Peripheral Nerve Injuries: Principles of diagnosis. By Webb Haymaker, Capt., M.C., A.U.S., neuropathologist, Army Institute of Pathology, Washington, D.C., and Barnes Woodhall, Maj., M.C., A.U.S., chief, Neurosurgical Section, Walter Reed General Hospital, Washington, D.C. 8°, cloth, 227 pp., with 225 illustrations. Philadelphia: W.B. Saunders Company, 1945. \$4.50.

The authors have incorporated in this work the newest information concerning their subject based on army experience. The book is intended for medical officers, as well as for medical students and civilian physicians who will be required to treat patients afflicted with nerve injuries. The volume is divided into three sections: the first discusses the principles of innervation, the second, the examination of the patient, and the third, the clinical features of plexus and peripheral nerve injuries. The text is copiously illustrated with photographs and line drawings. The book is printed on good paper, with a good type, and is easy to read. It is recommended as a reference text for all medical libraries.

Textbook of Abnormal Psychology. By Roy M. Dorcus, associate professor of psychology, University of California at Los Angeles, and G. Wilson Shaffer, dean of the College of Arts and Sciences, lecturer in psychology and professor of health and physical education, Johns Hopkins University, and psychologist Sheppard-Enoch Pratt Hospital, Towson, Maryland. Third edition. 8°, cloth, 547 pp., with 5 plates. Baltimore: Williams and Wilkins Company, 1945. \$4.00.

The publication record of this volume speaks well for its authority as a text on its subject. First printed in 1934, the second edition was published in 1939, and the third edition of 1945 is the eleventh printing of editions and reprints. The authors believe that there has not been any marked change in directional lines during the past five years and therefore have incorporated new material in the existing framework that has stood the test of time. Some of the material has been rearranged to obtain greater clarity for the student. The text has been written for advanced students in psychology, premedical students and medical students who already have had instruction in psychology. Scientific rather than popular terminology has been used wherever possible. An extensive bibliography of 833 references has been appended to the text, 365 of these have been added from the literature of the past five years. The text is well documented, and the book should serve as a reference source for all medical and university libraries.

Radiologic Examination of the Small Intestine. By Ross Golden, M.D., professor of radiology, College of Physicians and Surgeons, Columbia University, and director of the Radiological Service, Presbyterian Hospital, New York City. 4°, cloth, 239 pp., with 75 illustrations. Philadelphia: J.B. Lippincott Company, 1945. \$6.00.

The material contained in this volume has been assembled over a period of many years, and the text is based on instructional courses given by the author at various radiologic society meetings. The book has been written from the viewpoint of diagnosis, and no attempt has been made to discuss the treatment of disease. A comprehensive bibliography and an adequate index have been added to the text. The volume is well printed, with a good type, on good paper, making it easy to read comfortably.

Mass Radiography of the Chest. By Herman E. Hillehoe, M.D., medical director and chief, Tuberculosis Control Division, United States Public Health Service, and professional lecturer on tuberculosis control, George Washington University School of Medicine, Washington, D.C., and Russell H. Morgan, M.D., medical officer-in-charge, Radiology Section, Tuberculosis Control Division, United States Public Health Service, and assistant professor of roentgenology (on leave

LEONARD — Edward D. Leonard, M.D., of Newton Centre, died December 15. He was in his sixty-first year.

Dr. Leonard received his degree from Harvard Medical School in 1913. He joined the Newton Hospital staff in 1916 and became surgeon-in-chief in 1933, holding that position until last year, when he became an emeritus member of the staff. He was a fellow of the American Medical Association and a member of the American College of Surgeons.

His widow, a son and two sisters survive.

McNAMARA — John J. McNamara, M.D., of Brockton, died January 3. He was in his seventy-fifth year.

Dr. McNamara received his degree from Tufts College Medical School in 1900. He was formerly president of the Plymouth District Medical Society. He was a member of the Massachusetts Examining Physicians Association and a fellow of the American Medical Association.

Two brothers and a sister survive.

NEW HAMPSHIRE MEDICAL SOCIETY

DEATHS

ABBOTT — Clifton S. Abbott, M.D., of Laconia, died December 10. He was in his seventy-fourth year.

Dr. Abbott received his degree from Dartmouth Medical School in 1894. He had served as president of the New Hampshire Medical Society. He was a member of the American College of Surgeons and a fellow of the American Medical Association.

A sister survives.

CUTLER — Charles H. Cutler, M.D., of Peterborough, died December 22. He was in his seventy-ninth year.

Dr. Cutler received his degree from the University of Vermont College of Medicine in 1892. He was a fellow of the American Medical Association.

His daughter and two sisters survive.

TAYLOR — Herbert L. Taylor, M.D., of Portsmouth, died October 24. He was in his sixty-ninth year.

Dr. Taylor received his degree from Jefferson Medical College of Philadelphia in 1902. He was a fellow of the American Medical Association and the American College of Surgeons.

His widow and a daughter survive.

MASSACHUSETTS DEPARTMENT OF PUBLIC HEALTH

DISTRIBUTION OF PENICILLIN STOPPED

Effective February 1, the distribution of sodium penicillin by the Massachusetts Department of Public Health to private physicians for the treatment of gonorrhea will be temporarily discontinued, owing to the present shortage of this product.

When sufficient quantities have been accumulated to assure a surplus over the quantity needed by state institutions and co-operating clinics, distribution to private practitioners will be resumed.

MISCELLANY

REFRESHER COURSES AT HARVARD FOR DISCHARGED MEDICAL OFFICERS

Harvard Medical School will offer a series of six month refresher courses for medical officers discharged from the armed forces. These courses, under the supervision of Dr. Eugene C. Eppinger, assistant dean in charge of Courses for Graduates, will emphasize current scientific knowledge and theories and advances in the medical field. Instruction will be given by the regular members of the preclinical and clinical departments of the medical school. The first course is scheduled to begin on February 1.

In offering these courses, the medical school is attempting to assist physicians who, on separation from the services, wish to obtain the latest knowledge in the broad field of medicine in preparation for re-entering a civilian medical career.

CORRESPONDENCE

FACIAL EXERCISES AS AN AID IN THE TREATMENT OF ACNE

To the Editor—An important factor in the causation of acne is the accumulation of material in the sebaceous glands; the excretion does not keep pace with its formation. A black head forms, which sooner or later becomes infected, and a simple result.

Acne usually occurs on the face and neck and between the shoulder blades. Sometimes it appears on the chest. It generally does not occur on the arms, abdomen, lower back, buttocks or legs. In other words the lesions are found on the parts of the body that get little exercise. The face, where it occurs most frequently, is hardly exercised at all.

It is reasonable to suppose that, if the tone of the muscles were increased and strengthened, the excretion of sebaceous material would be facilitated. Its excretion would keep pace with its formation, and there would be no chance for a black head to form. Also the circulation would improve, which is an additional factor in the prevention of infection.

The required exercises to improve muscular tone are simple and easy to perform. First, the lower jaw is drawn down as far as possible and the face is stretched. This is done twenty or thirty times and repeated at convenient times during the day. This also exercises, to some extent, the muscles of the neck. The second exercise is the raising and lowering of the skin of the forehead. Thirdly, the lower jaw is pushed forward and backward many times. This exercises not only the muscles of the lower jaw but also those of the neck. And, finally, the neck muscles are exercised by bending the head forward and backward and by turning it from side to side.

Obviously, this treatment is entirely harmless and can be used in conjunction with other methods. It not only appears to be an aid in the cure of acne but also better the patient's looks, by improving the texture and color of the skin and by increasing the tone and strength of the facial muscles.

Acne is rare in this part of the country, and I have been able to experiment on only five cases. The first was that of a high-school boy of sixteen who had the worst case of acne that I have ever seen. The cheeks, forehead, chin and neck were covered with large and small pustules. The skin was greasy and rough and pasty. Treatment was begun three and a half months ago. The patient was much ashamed of the condition of his skin, he has been most co-operative and has faithfully performed the exercises. No other type of treatment was given during this period. After about three weeks the condition of his skin began to improve, and this has continued steadily since then. I saw him two weeks ago. His face was entirely free of pimples. The skin was still rough and scarred, but it had lost its pasty, greasy appearance and was firm and tight. The expression of his face had changed, and his looks were considerably improved. Acne was still present on the neck, but to a lesser degree than when I first saw him, possibly because he had not been able to exercise the muscles of his neck so efficiently as his facial muscles.

The other four cases treated by this method had moderate to mild degrees of acne. No other treatment except the exercises was employed. Although they have been using the treatment from only one to three months, all have shown definite improvement.

HODGKIN'S DISEASE*

VII. Treatment and Prognosis

HENRY JACKSON, JR., M.D.,† AND FREDERIC PARKER, JR., M.D.‡

BOSTON

THIS concluding paper of the series on various aspects of Hodgkin's disease concerns treatment and prognosis

TREATMENT

Hodgkin's Paragranuloma

It is difficult to give advice on the treatment of Hodgkin's paragranuloma. In view of the apparently localized nature of the disease in many cases and the excellent results of surgery in 2 of our cases, it seems reasonable to advocate radical dissection, followed by irradiation whenever the condition seems to be sharply confined to a readily accessible region. It must be pointed out, nevertheless, that there have been recurrences in 3 of 5 cases in which surgical excision was practiced, and this fact indicates that excision should be followed by prophylactic irradiation. Of the 2 patients who have been subjected to this routine, one is alive and entirely free from signs or symptoms thirty-four years after the onset of her disease, and the other, having remained symptom-free for twenty-four years, developed Hodgkin's granuloma and died three years later. If radical dissection does not appear to be warranted, fairly heavy doses of x-ray are indicated provided that not more than one area is involved.

Hodgkin's Granuloma

There is no specific treatment for Hodgkin's granuloma, nor is there likely to be one until its cause has been found. There are, however, a number of therapeutic measures that may be expected to prolong life and that will certainly alleviate the symptoms, often for a long period of time.

Three points should be borne in mind. First, in the great majority of cases, by the time the patient is first seen the disease has affected more than one organ. Second, virtually every organ and tissue may be involved sooner or later, and the utmost diligence must be exercised by the clinician to discover as early as possible any involvement of internal organs, so that appropriate therapeutic measures may be promptly instituted. Third, the disease may begin insidiously in an isolated and localized focus, and it is in all probability a circumscribed process at onset. This at least is our opinion, although we recognize that it is not shared by many students of the subject. In short, we believe that Hodgkin's granuloma has its origin in a single isolated focus, often, unfortunately, internal, and spreads insidiously, although rather rapidly, eventually involving many organs.

It is thus clear that if one is to have any hope of actually curing the condition, it must be discovered in its earliest stages and be promptly treated with the utmost energy. It is equally clear that both the clinician and the radiologist must constantly be on the lookout for evidence of involvement of internal organs, and must not content themselves with the gratifying results of treatment directed solely to superficial lymph nodes, which are in most cases merely the visible expression of an internal lesion. This point has become increasingly obvious in recent years.

A biopsy should be performed prior to therapy in all cases in which it is feasible. Unless this is done, and unless the removed lymph node is properly fixed and stained, one cannot be certain of the diagnosis, nor can the ultimate results of any form of therapy be accurately judged. Furthermore, a careful and complete physical examination, together with routine blood studies and x-ray examination of the chest, should be done in all cases at the first visit. Additional x-ray or laboratory studies may be indicated in specific cases.

*From the Thorndike Memorial Laboratory, the Second and Fourth Medical Services (Harvard) and the Mallory Institute of Pathology, Boston City Hospital; the Department of Medicine, Harvard University, and the Pondville Hospital, Massachusetts Department of Public Health. †This is the seventh and concluding article of a series of seven papers covering the various aspects of Hodgkin's disease.

§Associate professor of pathology, Harvard Medical School; pathologist-in-chief, Boston City Hospital.

of absence), University of Chicago 12°, cloth, 288 pp., with 93 illustrations Chicago The Year Book Publishers, Incorporated, 1945 \$3.50

The purpose of this small book is to bring together literature on mass radiography of the chest in one volume and to provide a general handbook of methods

The History of Surgical Anesthesia By Thomas E. Keys, M.A. With an introductory essay by Chauncey D. Leake, M.D., and a concluding chapter, "The Future of Anesthesia," by Noel A. Gillespie, M.D. 8°, cloth, 191 pp., with 43 illustrations. New York Schuman's, 1945 \$6.00

Major Keys has written a short history of the development of anesthesia from its earliest beginnings to the present time. Dr. Chauncey D. Leake has provided an interesting introductory essay in which will be found much material supplementing the text of Keys, and including his personal notes on anesthesia. In commenting on anesthesia collections, Dr. Leake omitted mentioning the valuable collection of the Boston Medical Library. The appendices contain a bibliography of selected references, a chronology of events relating to anesthesiology and allied subjects dating from 4004 B.C. to 1944 A.D., with a list of sources for this chronology, and a list of selected references for a history of surgical anesthesia arranged by subject and also arranged by author. In an appendix Dr. John F. Fulton discusses the Morton and Warren tracts on ether (Letheon). A comprehensive index is provided, and the text is well printed, with a good type, on good paper in the characteristic Schuman style.

The Modern Medical World. Portraits and biographical sketches of distinguished men in medicine By Solomon R. Kagan, M.D. 8°, cloth, 223 pp., illustrated. Boston Medico-Historical Press, 1945 \$6.00

This volume is a continuation of a series of other volumes on medical biography written by Dr. Kagan. Although there is an index of names, an alphabetical arrangement of the text would have been more useful than the present haphazard set-up. The selection of names contains many not commonly found in medical literature. This volume should be useful in all historical collections.

Yellow Magic. The story of penicillin By J. D. Ratcliff 12°, cloth, 173 pp. New York Random House, 1945 \$2.00

In this popular book Mr. Ratcliff tells the story of how penicillin was discovered and developed from the laboratory stage through the stage of clinical testing and trials to the present-day commercial production. The early chapters of the book are devoted to a history of the subject. There follow special chapters on the use of penicillin in the treatment of syphilis and gonorrhea, and in war wounds. One chapter is devoted to the work of the "heartless man in Boston," Dr. Chester S. Keefer. Dr. Keefer has written a foreword, and Dr. Morris Fishbein an introduction to the text. Mr. Ratcliff is a competent authority in the field of science, and he carefully prepared himself by visiting laboratories, hospitals and manufacturing plants preparatory to writing his short manual. The manual should prove useful to all medical and public libraries as a quick reference source on the history of penicillin.

The Newborn Infant. A manual of obstetrical pediatrics By Emerson L. Stone, M.D., associate clinical professor of obstetrics and gynecology, School of Medicine, Yale University, and attending obstetrician and gynecologist to the New Haven Hospital. Third edition, 12°, cloth, 314 pp., thoroughly revised. Philadelphia Lea and Febiger, 1945 \$3.25

This small book, first published in 1929, was originally the outgrowth of a short selective course of lectures given to the senior class of Johns Hopkins University School of Medicine. The work has two principal objectives to correlate and arrange in an orderly fashion a mass of data that are otherwise scattered through the medical literature and to emphasize the obstetrician's viewpoint and responsibility. The present revision aims to review concisely the accepted principles of physiology and pathology in the newborn infant and

to incorporate the added knowledge of the past decade in the field of medical practice. The text is well written, has a good index and should prove useful as a resume of its subject.

The Falling Sickness. A history of epilepsy from the Greeks to the beginnings of modern neurology By Oswald Temkin, M.D., associate professor of the history of medicine, Johns Hopkins University 4°, cloth, 380 pp., with 7 illustrations. Baltimore Johns Hopkins Press, 1945 \$4.00

Dr. Temkin, in this scholarly monograph, has written a history of epilepsy from the time of earliest antiquity to the time of Hughlings Jackson, about 1880. An extensive bibliography arranged alphabetically is appended to the text. The book is well printed, with a good type, on good paper and written in an interesting manner. It should be in all medical libraries and should prove interesting for public collections.

NOTICES

ANNOUNCEMENTS

Dr. Hollis L. Albright has resumed practice at 412 Beacon Street, Boston.

Dr. John J. Cincotti, recently discharged from military service, announces the opening of an office at 475 Commonwealth Avenue, Boston, for the practice of general surgery.

Dr. Robert J. Joplin, having recently returned from overseas duty with the Navy, announces the reopening of his office at 372 Marlborough Street, Boston, for the practice of orthopedic surgery.

Dr. Jost J. Michelsen announces the opening of an office at 311 Beacon Street, Boston, for the practice of neurological surgery.

Dr. Robert S. Palmer announces his return to the practice of internal medicine at 330 Dartmouth Street, Boston.

Dr. Theodore C. Pratt is resuming the practice of general surgery at 1101 Beacon Street, Brookline.

Dr. Salvatore Scelso announces the reopening of his office at 395 Commonwealth Avenue, Boston.

Dr. Grantley W. Taylor announces his release from military service and his return to private practice at 264 Beacon Street, Boston.

Dr. Winthrop Wetherbee, Jr., recently discharged from the Army, is resuming the practice of general medicine at 24 School Street, Boston.

SYMPOSIUM ON COMMUNICABLE-DISEASE CONTROL

The North Metropolitan District of the Massachusetts Department of Public Health, in co-operation with Boston University School of Medicine, will conduct a meeting "Looking Ahead in Communicable-Disease Control" on January 21 at Boston University School of Medicine, 80 East Concord Street, Boston. The morning session will be held from 10:00 a.m. to 12:00 noon, and the afternoon session from 2:00 to 4:30 p.m. The purpose of the meeting is to present to health workers and all others interested the recent advances in communicable-disease control. Discussions on biological, treatment with sulfa drugs and antibiotics, isolation and quarantine have been planned. In addition, a demonstration of nursing technique in the home and hospital will be presented, with a discussion by a bacteriologist and an epidemiologist.

(Notices continued on page 111)

the patient may seem at the time to be at death's door. Many patients have rapidly and markedly failed, only to return to comparative health when hospitalized, transfused and given appropriate irradiation. Gilbert¹ cites such a case from his own practice.

To obtain the best co-operation and thus the best results, it is wise to give the patient a general idea of what may be expected of x-ray therapy. It is not necessary to name the disease, it would obviously be unwise to picture the final outcome, and it is unnecessary to dwell on details. It is, however, proper to point out that the outward manifestations of the disease will diminish or even disappear, but with a warning that the same disease process may subsequently reappear in another place and that any untoward sign or symptom should be immediately reported. Only thus and by repeated routine examination can one hope to keep the disease in abeyance.

The question of marriage and pregnancy is, of course, of great importance. Both should probably be advised against, but, as Gilbert says, "these events occur in spite of us." If pregnancy should take place, it is necessary to decide whether it should be terminated. This question cannot be categorically answered. Three of our patients have become pregnant. One, a multipara, was aborted at her own request. She was alive and free from symptoms three years later. The other two, both primiparas, gave birth to normal babies, and each was well one and two years later, respectively, both children remaining well. Gilbert has had a similar although more extensive experience. The ultimate fate of the offspring cannot, of course, be foretold, but the present data seem to justify allowing pregnancy to go to term provided that one or both of the parents realize the potentialities.

In assigning to the fundamental disorder signs and symptoms that may properly be attributed to it, enthusiasm must be tempered with a modicum of knowledge of general medicine. One of our patients, a sixty-year-old Armenian, with "small Latin and less Greek" said that he was unable "to pass the water." What more tempting, in view of the fact that his disease was widely disseminated, than to see as a cause of this complaint a granulomatous process in the prostate and to irradiate that organ. Forthwith, he was indeed, "unable to pass the water." It was with much relief and some chagrin that we witnessed a complete and lasting disappearance of his symptoms following a prostatectomy for the simple, benign prostatic hypertrophy of old age.

In almost all early publications concerning irradiation, it was stated that although the symptoms could thus be alleviated, life could not be prolonged. It has recently become increasingly apparent that this is not the case. We agree with Gilbert and

others that the average duration of survival is prolonged. In 1923, Desjardins and Ford⁴ found that only a scant 10 per cent of their patients survived for more than five years. In 1932, Holfelder and Hummell (quoted by Gilbert¹) reported that nearly 18 per cent of their patients had passed the five-year mark. In Gilbert's series, 34 per cent fell into this category.

The results of irradiation vary within wide and unpredictable limits, as a rule, they are fairly satisfactory. Generally speaking, however, bone lesions are less radiosensitive than are foci in other organs. Lesions of the sternum, however, usually show a satisfactory response. In any event, relief from pain is often striking, and in some cases bone regeneration and repair have been observed. That excellent results may be obtained in such cases is attested by the following case.

E. W., (P 1935), a 20-year-old man was admitted to the hospital on January 5, 1935. In September, 1931, he had noticed a "swollen gland" behind the left ear. One month later this became painful and other lymph nodes appeared in the left side of the neck. One of these was removed, and a diagnosis of Hodgkin's granuloma was made. During the next 5 years lymph nodes appeared from time to time in the neck, axillas and groins, but always diminished or disappeared after appropriate high-voltage x-ray treatment. In addition, the patient was periodically troubled by intense generalized itching, which was partially controlled by spray x-ray treatment and by viosterol in large doses. His general health however, continued to be good, and he remained mentally and physically active.

In June, 1936, the patient complained of pain, especially on motion, in the lower lumbar region. This was relieved by the administration of 60r by spray to the body anteriorly and 100 r posteriorly. In October of that year there were no palpable lymph nodes, and the patient's general condition was excellent, — although he had lost some weight, — but he complained of intense pain in the lumbar region, particularly on the right side.

Physical examination showed a marked lumbar scoliosis on the left side and intense contraction of the lumbar spinal muscles on the right side. X-ray films showed a destructive process of the bodies and transverse processes of the 1st and 2nd lumbar vertebrae. There was a slight degree of vertebral collapse. Six hundred roentgens was given over the involved area, and the pain completely disappeared. In January, 1937, there was some return of the pain but complete relief was again obtained after the administration of 400r to the lumbar region.

In May, 1937, the patient again complained of considerable discomfort in the lumbar region, and x-ray examination showed an increase of the destruction of the 1st and 2nd lumbar vertebrae. Nine hundred roentgens was given over the involved area, and in October there was evidence that new bone was being laid down in the bodies of the vertebrae and that fingerlike processes of new bone were reaching out into the soft tissue to bridge the existing defect. The radiologist noted that there appeared to have been an arrest of the process and a laying down of calcium deposits in the ligamentous structures surrounding the lateral portions of the 1st and 2nd lumbar vertebrae on the left.

The general result was that in spite of the bony destruction there was a partial and fairly effective ankylosis of the spine. Nine hundred roentgens more was given, and the patient continued to be in reasonably good health and was able to control the discomfort in the lumbar region by salicylates. In spite of the marked bone lesion he was able to swim, play tennis and ski, although he complained, with a smile, that a left hand telemark was hard to accomplish.

By October, 1939, the lesion of the lumbar spine had extended to include the body of the 12th dorsal vertebra. There was, however, no increase in symptoms, and the patient was still active in athletics 8 years after the initial symptoms.

The most valuable therapeutic measure is irradiation. On this point all are agreed, but there is no consensus concerning the best method of applying it. Indeed, it is clear that in a disease showing such diverse and protean manifestations and running such an unpredictable and variable course, this is almost inevitable. The treatment must necessarily be adapted to the individual patient, the results of therapy can be adjudged only over a long period of time and with due regard to the varied manifestations of the disease.

There are various schools of thought regarding the proper type of irradiation, and one may choose for oneself that which seems the most logical, the most promising and the most suitable.

Gilbert¹ has covered this entire subject with care, and to his article the reader is especially referred. A partisan of high-voltage x-ray, he advocates wide irradiation of the regions patently invaded as well as those suspected of invasion, and contends that it is essential to irradiate widely enough to be reasonably certain of subjecting the entire involved regions to the action of the rays. In consequence of his belief that local recurrences begin in granulomatous islands subjected to inadequate irradiation, his initial doses are relatively large. Panteleoroentgen therapy is, in his opinion, of more harm than good.

His therapeutic regime is briefly as follows. Diagnosis is made by biopsy whenever feasible. Involved areas and regions suspected of being involved by reason of the symptoms are irradiated, from 180 to 200 kilovolts being used through portals up to 20 by 20 cm. To each area are given fractional doses of approximately 200r every other day until the desired total has been delivered — a minimum total depth dose of 500r to each focus. The paravertebral, para-aortic and retroperitoneal nodes are irradiated if general signs, such as fever, pruritus and asthenia, persist after successful irradiation of apparently localized disease elsewhere. Treatment is renewed only if evidence of recurrence is seen.

Sixteen of Gilbert's 52 patients treated in this manner were still alive at the time of his report, of these, 9 (17 per cent of the total) had survived five years or more and 3 had survived for ten years or more.

In recent years, our own therapeutic approach has been similar to that of Gilbert. A 250-kilovolt machine is used. Each area involved or suspected of being involved is treated through a portal of sufficient size to embrace the entire field, in fractionated doses until the required amount has been given. It is probably best to give comparatively small doses to any given area if the disease is widespread, but many authorities believe that large, heavy doses should be given if the condition appears to be confined to one region. No further irradiation is resorted to unless there is a recurrence.

Recently, we have in certain selected cases used a supervoltage (1000-kilovolt) x-ray machine. It is too early to come to any conclusion concerning the relative merits of this method of irradiation. All patients are seen at frequent intervals, — two weeks to three months, — and great diligence is exercised in attempting to discover, by one means or another, any new focus of disease. Any persistent symptom or sign not explainable on other grounds is regarded as being due to Hodgkin's granuloma and appropriate irradiation is given. This is an important part of the treatment, irrespective of the exact type of irradiation used. Of the 35 patients in our series still alive on January 1, 1945, 17 (47 per cent) have survived for five years or more. Thus, 16 per cent of the patients in the entire series who were subjected to systematic treatment and adequately followed survived for five years or more.

It is our belief that the internist and the radiologist should care for the patient conjointly and that all details of x-ray therapy should be left to the radiologist. No matter what type of x-ray therapy is used, — and it is obvious that competent authorities advise varying methods of attack, — certain practical points should be borne in mind.

Extremely large mediastinal masses must be treated with great caution, for not infrequently they are extremely radiosensitive, in which event too rapid destruction by excessive amounts of x-ray may result in the organism's being flooded with products of necrosis, which may bring about highly toxic manifestations or even death.

The acute form of Hodgkin's granuloma, accompanied by high temperatures, an elevated white-cell count and the signs and symptoms of an acute infection, must be treated with great care and conservatism. A rapid rise in temperature calls for temporary cessation of therapy. The situation is somewhat analogous to that seen in acute leukemia.

The presence of active tuberculosis contraindicates irradiation of the lungs and mediastinum in the usual doses, as does renal insufficiency, especially if associated with nitrogen retention.

The presence of unexplained fever, vague gastrointestinal disturbances, fleeting abdominal pains, generalized itching or a persistently elevated white-cell count, with an increase of polymorphonuclear leukocytes, usually indicates the presence of diseased lymph nodes deep in the abdomen or in the para-aortic region, and irradiation of these areas often causes a remission of the symptoms.

We have been increasingly impressed with the wisdom of relentless treatment even in the face of what appear to be overwhelming odds. Of course a point is reached when further irradiation is fruitless and even harmful, but this does not usually occur until after many courses of treatment, and it is remarkable what may be accomplished in the relatively early stages of the disease even though

until the time comes when it can be truthfully said that operative interference is uncalled for. Too often one waits to see what will happen. Too seldom does one proceed radically. Such is the early history of many incurable diseases. The paradox is that when the lymphadenopathy is still possibly amenable to complete surgical removal, it is liable to be regarded as benign, whereas when it has become inoperable, one contents oneself by saying that it always has been so.

Certain authors have claimed excellent therapeutic results with Hodgkin's granuloma confined to the gastrointestinal tract, but so far as our experience goes, these patients fare badly, for in no case did a patient survive for more than eighteen months after the initial symptoms, and the average duration of life from onset to death was only nine months. Patients with gastrointestinal lesions incidental to a generalized process similarly appear to have an unfavorable prognosis, if the figures derived from such a small series may be regarded as significant.

The psychologic aspects of treatment should never be overlooked. If the patient is a physician, he should be told the precise diagnosis. The details of the treatment and prognosis need not, and indeed should not, be dwelt on. We have cared for a considerable number of doctors afflicted with Hodgkin's disease or allied conditions, and all but one have borne their disease with cheerful stoicism from beginning to end. In the single exceptional case, serious family difficulties unquestionably contributed to the patient's mental undoing.

If the patient is a layman, it is probably best not to name the disease, even though — as is usually the case — one is asked what it is. Practically all patients are content with evasive answers, and rarely press the point if they are casually told that some lymph nodes are enlarged for some obscure reason and that much can be done to alleviate their symptoms. The mere assurance that symptomatic improvement can be achieved almost always sets the patient's mind at comparative ease, and the initial therapeutic success tends to tide him over subsequent recurrences, even though these may be less amenable to such therapeutic measures as are available. As time passes, the patient himself often comes to the realization that he is going to have the disease the rest of his life, and this recognition gradually changes to an awareness that he is sure to die of the disease. This inner awakening to the bitter truth hurts far less than would a blunt statement on the part of the attendant physician. Less frequently the patient imperceptibly — to himself — grows worse and worse, and he is never genuinely conscious of the impending end. Still less frequently sudden death occurs even when the patient appears to be doing well.

Very rarely one encounters a patient who asks how long he will live, and means it. In such cases an entirely plausible reason is always given for

wishing this exact information. The absence of such a logical reason is usually sufficient evidence that the patient is not truly serious in his questioning. Even so, dogmatism must be avoided, the course of the disease is too erratic. For example, one young man asked how long he would live. From his former physician he had learned the diagnosis. When asked why he wished to know, he replied calmly that he wanted to plan his life in accordance with the prognosis. He was told that he would live for one year, and at his request he was shown the evidence on which this statement was based. "All right," he said, "I will build a house — that takes a year." Six years later, the physician who had made the prognosis received a note in which the patient remarked that the skiing was excellent in the mountains and invited him to come there for the weekend. The patient died four years later following a major surgical operation. The individual patient is not the average patient, and the rules of Hodgkin's disease are made to be broken.

It should be recognized that patients with this disease are unusually quick to grasp the significance of any remark arising from the physician's awareness that the end is approaching, indeed, they exaggerate it. In several of our cases, fear and despair has supplanted hope and a sense of security. For example, a patient who lived in a distant town had done unusually well for five years, but then began to fail, although without realizing it. It was suggested that he get in touch with a local physician so that there might be someone at hand who was familiar with his case. On reaching home he telephoned his son and said, "Well, my death warrant has been signed." In a week he was dead. It may be argued that he would have died anyway, but this is doubtful, and at least he would have died in peace had the subject been brought forward earlier and more tactfully.

In all cases some responsible member of the family, not necessarily the nearest of kin must be told in lay terms the diagnosis and the probable prognosis. Even here, however, one must be cautious, for as has been repeatedly said, each case is a law unto itself.

Hodgkin's Sarcoma

The treatment of choice in Hodgkin's sarcoma, as in other forms of Hodgkin's disease, is irradiation, yet it must be admitted that there is no convincing evidence that such treatment, even when given in full doses, is of much avail. Not infrequently, virtually no response is obtained, a result that in Hodgkin's granuloma is extremely rare. In the presence of anemia, transfusions are helpful. The fact that in most cases the condition arises in an internal organ or in the retroperitoneal lymph nodes and is thus less likely than otherwise to be diagnosed at an early stage militates still further against successful therapeutics.

and 3 years after the demonstration by x-ray of a destructive process in the spine involving at least three vertebrae. Early in 1940 there developed considerable pain in the lower back and in both legs, which gradually increased in severity and could be controlled only by opiates. The patient remained cheerful, however, and his physical activities were limited solely by the pain, which became so severe in the fall of 1940 that a dorsal cordotomy was performed. The operation was entirely successful in so far as relieving the pain was concerned, but the patient failed rapidly and died in December, 9 years after the initial symptoms.

In addition to irradiation, three therapeutic adjuncts must be considered: blood transfusions, general care and surgery.

Some authors object to transfusions and believe that they are rarely of benefit and may even be harmful (Wallhauser⁵). We,¹ on the contrary, agree with Gilbert that they are of inestimable value, and it is doubtful whether the reactions to which some authors have drawn attention would occur if careful attention were paid not only to the group but also to the subgroup of both donor and recipient. This is particularly important if repeated transfusions are necessary at rather long intervals, for although, for instance, A_1B_1 blood may produce no reaction on the first transfusion in an A_1B_1 recipient, the patient may gradually build up antibodies against B_1 in such a manner that subsequent transfusions even from the same donor are accompanied by violent reactions.⁶ It is our custom to transfuse patients whose red-cell count is 3,000,000 or below unless they are in the terminal stages of the disease. We have never seen an untoward reaction when the bloods were properly matched in both the major and the minor agglutinations.

Iron in the form of ferrous sulfate may be of benefit.

It is obvious that general care is of importance in any chronic condition, and this is no less so in Hodgkin's granuloma. Plenty of rest, ample food that is high in vitamins and the other essential elements, fresh air and sunlight within the tolerance of the patient are all of real value. Not a few patients volunteer the statement that their sense of well-being is greatly enhanced if they stay out-of-doors in the sun.

Obvious foci of infection should be removed, for they undoubtedly have a provocative influence on the condition. For itching, in addition to the irradiation referred to above, local applications of 0.5 per cent phenol in olive oil may be tried. For pain, particularly that arising from bone lesions, salicylates in full doses often produce surprisingly good results. One of our patients had a destructive lesion of the lumbar spine associated with marked pain. X-ray therapy brought about a regression of the bone lesion, but the pain, which was apparently dependent on the resulting scoliosis and muscle spasm, persisted. For several years it has been controlled by large doses — 2 to 6 gm — of aspirin a day, and the patient is able to live a normal and indeed active life.

Our experience with cordotomy for pain has been most unsatisfactory, although there are no doubt cases in which it is of benefit. In 1 case, the skillful injection of the posterior roots with alcohol was followed by complete relief of pain. There was no further discomfort until the patient's death a year later.

The question of surgical intervention is a moot one. First championed by Yates and Bunting in 1917,⁷ it has since fallen into disrepute. The great majority of writers on the subject have concluded that it is useless, some because they have seen it fail again and again, others because they have seen the rapid return of lymph nodes in the operative field, and still others because of their belief that Hodgkin's granuloma is always a generalized disease from the start — a belief for which there are no valid grounds. It is true that by the time the patient first seeks medical advice, the process is usually widespread or at least inoperable. It is also true that in many cases the original focus is internal and therefore inaccessible, but both clinical experience and autopsy findings tend to show that the disease begins in one focus and spreads from it — slowly in some cases and rapidly in others.

Gilbert writes: "Surgical procedures have shown themselves useless, they do not influence the evolution of the disease. Local recurrence or extension develops shortly after operation, except in the benign, local and peripheral forms in which the lymph nodes are still movable." Baker and Mann⁸ adopt a somewhat more militant and optimistic attitude. They cite the first and second cases in their series, in each of which there was performed surgical excision of the diseased tissues, associated with deep x-ray therapy. The first patient was alive and well thirteen years and the second eleven years after operation. It is the opinion of these authors that when the lymph-node enlargement is localized, surgical excision should be practiced and the area subsequently irradiated. We share this view, with the full recognition that suitable cases are indeed rare and that even in them some hidden focus not apparent at the time of operation may frustrate attempts at cure. Much has been said and written about the necessity for early diagnosis in cancer, and it is generally appreciated that in early recognition of this disease lies the best hope of true cure. The same can be said for Hodgkin's granuloma.

Two of our patients with this disease have been subjected to radical excision of cervical lymph nodes. One was alive and free from signs and symptoms of disease ten years after operation, and the other is alive and well seven years after operation. Both patients were children. It is obvious that in view of the extremely variable course of the disease, no conclusions can be drawn from these cases, and at best the results are only suggestive. Too often, however, one hesitates, argues and procrastinates.

ur patients died in less than six months after the pparent onset, and 11 survived for eight years or more, 7 of these being alive and in reasonably good health for eight to twenty-two years after the first symptom

If these two groups of cases, examples of the prognostic extremes, are contrasted, certain definite points stand out. The onset in the rapidly fatal cases was usually suggestive of an acute infection or indicated internal involvement. Chills, dyspnea, cough, fever, abdominal pain, sweating and dysphagia were seen at the very beginning of the disease, and only 7 of the 15 patients had palpable superficial lymph nodes when first seen, although all but two had peripheral lymphadenopathy prior to death (Table 6). In almost all cases in which cough,

and Leonard¹⁰ were unable to determine any connection between the time of onset of pulmonary symptoms and the time of death. It appears, however, that these authors dated the onset of pulmonary involvement from the first pulmonary symptoms, which may well have been due to mediastinal or hilar node involvement rather than to actual implication of the parenchyma. Similarly, Pierce et al¹¹ state that the roentgenological appearance offers no criteria for prognosis.

Our own experience has been somewhat more definitive. No patient in whom pulmonary lesions were demonstrated at autopsy lived for more than eight months after these changes had been discovered during life, and the great majority died within three months. Three patients who gave x-ray evidence of pulmonary invasion from mediastinal or hilar nodes survived for over two years after the demonstration of these changes, but in no case was there autopsy confirmation of the reported pulmonary involvement. It is perhaps of some interest that all 3 of these patients had an unusually long course, averaging over eight years. No definite conclusions can therefore be drawn, but it seems probable that involvement of the lung parenchyma is associated in many cases with rapidly advancing disease.

Ziegler¹² concluded that Hodgkin's disease runs a more rapid course in children than in older patients. Uddströmer⁹ believed the reverse to be true. Our own experience is that age alone has little or no influence on the prognosis.

That the disease may run an extremely rapid course has been already pointed out. For example a six-year-old girl was noted by her parents to have enlarged lymph nodes in each side of the neck in December, 1933, and one week later developed cough and fever. She died of respiratory failure on January 10, 1934, within six weeks of onset.

In sharp contrast is the following case.

A P, a 10-year-old boy, in 1915 developed a painless lump in the left side of the neck. It gradually increased in size until November, 1917, when it was removed by surgery. Histologic examination of the node showed the typical picture of Hodgkin's granuloma (MGH-S17-11-58).

On admission to the hospital on December 17, 1917, physical examination was entirely normal except for the presence of several firm lymph nodes, varying from 0.5 to 1.0 cm in diameter in the anterior triangle of the right side of the neck. No lymph nodes were palpable in any other area. The red-cell, white-cell and differential counts were essentially normal.

Between December 27 and May 31, 1918, a total of 6100 mc. hr of radium (2 mm. of lead and 2 cm. of gauze screening) was given to the left side of the neck and the left axilla, although there were no palpable lymph nodes in the latter area. The cervical lymph nodes disappeared, and the patient was not seen again until December 20, 1924. At that time he was in excellent condition, and the physical examination was entirely within normal limits.

He returned on August 22, 1930, when a 2-cm. node was found under the left jaw. There were many carious teeth in the lower jaw. The node was removed on September 6. The microscopic diagnosis was Hodgkin's granuloma. A full suberythema dose of x-ray was given at 250 kilovolts over the left side of the neck.

Since that time the patient has remained entirely well. When last seen in December, 1939, 22 years after onset,

dyspnea, chills, sweats and fever were present at the onset of the disease, death occurred within six months. One cannot of course expect this rule to hold in every case, but it appears to be a helpful prognostic guide. As Uddströmer⁹ points out, however, the disease process may have been in existence much longer than the symptoms indicate when it has its origin in the hilar, mesenteric or retroperitoneal lymph nodes, and the actual duration of the disease may therefore be longer than is evidenced by the available clinical data.

Of the 11 patients who survived for eight years or longer, and 8 of whom are now alive and in reasonably good health, 8 sought medical advice for simple, painless localized lymphadenopathy without any associated signs or symptoms. One had in addition a certain amount of general fatigue, 1 complained of dyspnea, and 1 entered the hospital for the first time with a complaint of weakness of the legs.

The contrast between these two groups is sufficiently arresting to demand attention. By and large, in the rapidly fatal cases there was an onset suggestive of an acute infection, whereas in those of long duration the patients presented themselves with simple lymphadenopathy, only occasionally associated with symptoms of generalized disease. The more nearly a given case approaches one or another of the extremes, the more does the course run true to form.

Most students of this subject agree that no definite relation exists between the onset of pulmonary findings and the progress of the disease. Falconer

If the condition is discovered at an early stage, when the lesion is comparatively localized, radical surgical intervention appears to be indicated, but we have not encountered any such case

PROGNOSIS

Hodgkin's Paragranuloma

For certain forms of malignant disease, such as osteogenic sarcoma, a maximal time of survival may be set with some degree of accuracy, and in the great majority of cases the physician may rest assured that an actual cure has been effected if the patient survives this date. This situation does not obtain in Hodgkin's paragranuloma.

The prognosis of this disease is comparatively good. Of 26 patients followed to date, 14 (54 per cent) have been alive and free from symptoms for five years or more, and 5 have survived a fifteen-year period (Table 1). It is of considerable sig-

nificance that of the 12 patients who have died, 5 succumbed to diseases entirely unrelated to their disease, the remainder developed Hodgkin's granuloma and died in less than ten years after onset.

Hodgkin's Granuloma

Hodgkin's granuloma is usually regarded as a fatal condition, leading to death in one to three years. In general such is the case, yet it is important to remember that the individual patient is not the average one, that the span of life from onset

TABLE 2 *Average Duration of Disease from Onset to Death according to Age at Onset in Cases of Hodgkin's Granuloma*

varies within wide limits, and that rarely a patient survives without evidence of active disease for so long a time that an actual cure may be considered at least possible.

In Table 2 is shown the duration of life from the first sign or symptom that could properly be con-

sidered as due to the disease itself in the 136 cases of our series in which the patients died of the disease after being followed throughout its course. Three patients died of entirely unrelated causes and are therefore not included. It is apparent that the average length of life from onset to death is approximately two and a half years. Uddström's¹ data, based in a like manner on 494 fatal cases, are

in essential agreement with ours, and Wallhauser,² from a review of the literature, has come to essentially the same conclusions. These average figures, however, by no means tell the whole story. Thirteen per cent of our patients lived for five years or more after onset, and 1 died eleven years after onset (Table 3). About 30 per cent, therefore, lived definitely longer than either those in the average or median group, and 13 per cent lived twice as long.

When one considers those patients who were still alive, a somewhat different picture is seen (Tables 4 and 5). It is apparent that the duration of the

series — 69 living cases — or can be attributed to the increased efficacy of more recent x-ray therapy is a question that cannot be answered with any degree of assurance. The fact remains, however, that of these 69 patients, 28 (40 per cent) had had their disease for five years or more and that an additional 6 per cent had survived a ten-year period.

The question therefore naturally arises whether at the onset there are any criteria by which one can foretell the course of the disease. Fifteen of

THE WOLFF-PARKINSON-WHITE SYNDROME

CAPTAIN NORMAN H BOYER, MC, A US*

TO THOSE with extensive electrocardiographic experience, especially if it includes a large proportion of young adults, the finding of the pattern of a short PR interval and a prolonged QRS complex comes as no great surprise. That it is not a rare occurrence, as might be concluded from the many papers in the literature reporting one or two cases, needs to be emphasized, because this combination is still all too frequently misinterpreted as being of clinical significance. Such misinterpretation might be considered negligible if the electrocardiographic findings occurred but rarely. On the other hand, if the pattern is as frequent as experience indicates, it becomes important, particularly in the military service that it receive wider publicity.

During the routine interpretation of electrocardiograms in an Army general hospital, this curious pattern seemed to appear with greater frequency than had been expected. Accordingly, the last 2000 electrocardiograms were reviewed. The pattern of a short PR interval and a prolonged QRS complex was encountered at one time or other in 7 cases. Since the records represented 1356 patients, the incidence was 0.5 per cent. At the present strength of the armed forces this is equivalent to about four divisions. If even a small percentage of such men were to be returned from combat areas with diagnoses of bundle-branch block, a considerable loss of manpower would result. Furthermore, even when such a record is later accurately evaluated in another hospital, it is difficult and often impossible to salvage the patient because of a firmly entrenched cardiac neurosis or neurocirculatory asthenia. Moreover, when and if these patients are returned to civilian life, they will probably remain partially ineffective.

Brief summaries of these cases follow, together with an illustrative electrocardiogram.

CASE 1 A 19-year-old soldier was admitted to the hospital because of recurrent episodes of dizziness, shortness of breath, palpitation and occasional fainting. These symptoms had been present since infancy and were usually brought on by exertion. Early in life the patient had been cautioned about his heart because of a murmur. He was admitted to an overseas hospital, where a precordial systolic murmur was heard, and was evacuated with a diagnosis of interventricular septal defect and bundle-branch block.

Examination revealed an inconsequential precordial systolic murmur and an electrocardiographic pattern of a short PR interval and a prolonged QRS complex. The patient was made to exercise to the point of shortness of breath and dizziness, without any change in the blood pressure, cardiac rhythm or electrocardiographic pattern. The intravenous injection of 2 mg of atropine sulfate also failed to alter the electrocardiogram. Fluoroscopic examination of the heart revealed no abnormalities. The patient was considered to have severe neurocirculatory asthenia.

CASE 2 A 34-year-old soldier entered the hospital because of attacks of paroxysmal tachycardia, which had begun 5

years previously. Between attacks he had been symptom-free. Physical and roentgenographic examinations were normal. Electrocardiograms consistently showed a short PR interval and a prolonged QRS complex, which were unaffected by atropine.

CASE 3 A 34-year-old soldier was admitted on his return from overseas with a diagnosis of rheumatic fever. He had had a probable attack of rheumatic fever at the age of 4 and an authenticated attack in an Army hospital in September 1943. He was discharged back to duty and fared well until June 1944, when he had a recurrence of joint pain, with fever and an elevated erythrocytic sedimentation rate. Several electrocardiograms were said to have revealed intraventricular conduction defect. The patient was evacuated to the United States and on arrival had no complaints.

The physical examination was normal. Review of the previous electrocardiograms showed the pattern of a short PR interval and a prolonged QRS complex, but the record obtained on admission was normal save for a single beat, which was at first interpreted as a late ventricular ectopic beat. A review of the previous records made it apparent, however, that this beat was identical with the complexes previously present. Following the subcutaneous administration of 1 mg of physostigmine the pattern was reproduced in all cycles. There was no clinical or laboratory evidence of active rheumatic fever or of organic heart disease.

CASE 4 A 25-year-old soldier with a history of possible rheumatic fever at the age of 12 was admitted to an overseas hospital because of multiple-joint pain, without objective swelling, redness or local heat. There was no fever, leukocytosis, or elevation of the erythrocytic sedimentation rate. Electrocardiograms, however, were interpreted as showing left bundle-branch block. Largely on the basis of the latter report the patient was considered as having active rheumatic infection and was evacuated to the United States.

On admission there were multiple complaints including fleeting joint pain, precordial pain, palpitation and shortness of breath. Physical, laboratory and roentgen-ray examinations were normal. Electrocardiograms, which were identical with previous records, showed the pattern of a short PR interval and a prolonged QRS complex. The patient was considered to have a psychoneurosis, including neurocirculatory asthenia and psychogenic "rheumatism." The electrocardiogram is reproduced in Figure 1.

CASE 5 The clinical record was not available in this case, but the final diagnosis was severe neurocirculatory asthenia.

CASE 6 A 30-year-old soldier was seen because of attacks of paroxysmal tachycardia for the last 4 years. In the intervals between attacks he was essentially symptom-free. Physical and roentgen-ray examinations of the heart were normal. The electrocardiogram showed a short PR interval and a prolonged QRS complex.

CASE 7 A 33-year-old soldier was referred for an electrocardiogram before shock therapy for catatonic schizophrenia. Although a history of sharp precordial pain and shortness of breath was obtained, the patients had no complaints and answered all leading questions in the affirmative. The history was accordingly discounted. Physical and roentgen-ray examinations of the heart were normal. The electrocardiogram revealed a short PR interval and a prolonged QRS complex. Shock therapy was not employed because of an erroneous diagnosis of bundle-branch block.

DISCUSSION

The mechanism of this curious electrocardiographic pattern, first clearly defined by Wolff, Parkinson and White,¹ still remains unexplained. The theory of a short-circuiting bundle between the auricles and ventricles, proposed by Wolferth and Wood,² has been almost universally accepted by recent authors. The demonstration by Butterworth and Pindexter^{3,4} that the pattern can be

*Assistant professor of medicine, Boston University School of Medicine, and assistant physician, Evans Memorial Massachusetts Memorial Hospitals (on leave of absence).

he was free from symptoms and physical examination disclosed no abnormalities

Between the extremes of these two cases lie the majority of cases. It is well to bear in mind that it is often difficult to predict the course with any degree of accuracy. That such is indeed the fact is well illustrated by a case in which the patient had at onset symptoms of a generalized disease and signs of involvement not only of lymph nodes but of bone, but was alive and at work twelve years later.

Rarely sudden death occurs. MacCallum¹³ describes a case in which the patient leaned forward to drink a cup of tea and died instantly. Autopsy showed that the odontoid process of the axis had been completely destroyed by the disease and that the slight effort of motion had dislocated the spinal column so as practically to cut the cord in two. One of our patients, a boy of fifteen, was eating his luncheon in comparative comfort. In the midst of the meal, he sighed, laid down his knife and fork and expired. Permission for an autopsy was not obtained. As Wallhauser⁶ points out, the manner and time of death depend on several variable factors, chiefly the course, — acute or chronic, — the organs and situations involved, the degree of anemia, secondary infections, the quality of the patient's resistance and the treatment. The importance of the last two factors is too frequently overlooked.

It is difficult to evaluate the prognostic significance of bone lesions in Hodgkin's disease. Many patients in our series so affected died within less than one and a half years of x-ray discovery of the lesion and 63 per cent died within less than a year after it. A patient with a massive erosion of the sternum, however, was in seemingly good health and hard at work twelve years after its discovery, and of the patients who died within a year of the demonstration of the bone lesion, 33 per cent had already had unequivocal signs of Hodgkin's disease elsewhere for three years or more. From the available evidence it does not appear that bone lesions materially alter the outlook. In this opinion Uehlinger¹⁴ concurs.

Hodgkin's Sarcoma

None of our patients with Hodgkin's sarcoma lived for more than three years after onset, and nearly 60 per cent died within two years (Table 7).

Again one sees the sharp contrast between Hodgkin's sarcoma and Hodgkin's granuloma. In our experience, the former is invariably fatal within a comparatively short period of time, whereas the latter usually runs a relatively benign course and in rare cases is actually cured.

intrinsic deflection is delayed for 0.11 second in the ectopic beat, as compared with 0.04 second in the normal beats. The available material has not allowed exhaustive study of precordial leads, but at present it is fair to say that the chest leads in the

1 had schizophrenia, possibly with neurocirculatory asthenia. That the relatively high incidence of neurocirculatory asthenia is not explainable on the basis that it is such patients who, in this age group, are likeliest to have electrocardiograms made is attested by the fact that by far the majority of the 2000 records reviewed were made in patients in various stages of rheumatic fever. Only one patient (Case 3) was in the latter group, and he had no symptoms whatever.

Two explanations of the association of this electrocardiographic pattern and neurocirculatory asthenia are plausible. First, the deranged nervous system may actually produce the pattern. This theory is supported by the frequent, although by no means invariable, alteration from abnormal to normal or from normal to abnormal patterns induced by drugs known to act on the vegetative nervous system. Second, the abnormal sequence of excitation may result in cardiac sensations that, in certain susceptible persons, may lead to "heart consciousness," neurocirculatory asthenia or cardiac neurosis. Although the diagnosis of organic heart disease made on the basis of the electrocardiogram undoubtedly contributed to an increase in symptoms in the present group, it was not the cause of the symptoms of neurocirculatory asthenia, for the complaints in all the patients in whom this diagnosis has been made were present before the electrocardiogram was obtained.

The recent report of sudden death in a patient who had previously shown the Wolff-Parkinson-White pattern⁶ should not lead to undue emphasis on the possibility of such a disaster. The rarity of sudden death in young persons without clear pathologic entities and the apparent frequency of the abnormal electrocardiographic pattern warrant accepting a slight risk, if such exists, to avoid creating or adding to anxiety states.

SUMMARY

The electrocardiographic pattern of a short PR interval and a prolonged QRS complex has been encountered rather frequently in an Army general hospital, the incidence being 0.5 per cent of patients in whom electrocardiograms were made. Several of these patients had been unnecessarily evacuated from combat areas.

Provided that this experience is not unique, it seems likely that many more soldiers will be unnecessarily evacuated unless those responsible for electrocardiographic interpretations familiarize themselves with the pattern and recognize its probable benignity. The frequency of psychoneurosis in the present series of patients was high, and particularly in such patients it is desirable to avoid adding to their symptoms with a diagnosis of bundle-branch block or myocardial damage.

The mechanism of this pattern is still unexplained. The theory of aberrant conduction tissue between

FIGURE 2 Electrocardiogram Showing Trigeminal Rhythm Due to Regularly Recurring Ventricular Ectopic Beats. Note that the onset of the intrinsic deflection in the ectopic beats varies with the position of the precordial electrode, as it does in bundle-branch block.

Wolff-Parkinson-White pattern do not resemble those from either ventricular ectopic beats or bundle-branch block.

In the first clear clinical description of this pattern, that by Wolff, Parkinson and White¹ it was said to be usually associated with paroxysmal tachycardia. In the present series only 2 patients had clear-cut paroxysmal tachycardia, 1 had no symptoms, 3 had neurocirculatory asthenia, and

reproduced in animals by the artificial introduction of such a short circuit attests to the logic of the theory, but neither this experimental work nor the histologic demonstration of an auriculoventricular band in such a case by Wood, Wolferth, and Geckeler⁵ absolutely establishes the mechanism.

There are several features of this syndrome that are not satisfactorily explained by the theory of an

from the right and the left precordial position. This feature distinguishes the precordial lead pattern from that of bundle-branch block, in which the interval between the onset of the QRS complex and the intrinsic deflection is prolonged over the blocked ventricle but is normal over the unblocked ventricle. Equal blocking over both ventricular areas, as seen in Figure 1, offers a serious objection to the theory

FIGURE 1 Electrocardiogram in Case 4

Note that the onset of the intrinsic deflection is equally delayed in all precordial leads

accessory auriculoventricular band. For example, the pattern apparently disappears with advancing age, yet vagal tone increases rather than decreases with age. Inasmuch as an increase in vagal tone may reproduce the pattern when the electrocardiogram is normal, as in Case 3, and a decrease in vagal tone produced by exercise or atropine may temporarily abolish it, it is curious that it is not more frequent in older people. Regular disappearance of the anatomic structure after a certain age seems unlikely.

A somewhat more important objection to the theory of an accessory band is to be found in the failure of multiple precordial leads to establish early excitation of one or the other ventricle. Figure 1 shows a series of CF leads in Case 4. It may be seen that the interval from the beginning of QRS complex to the onset of the intrinsic deflection—that is, the first rapid downward movement of the string—is the same—about 0.08 second—in leads taken

of abnormally early excitation of one of the ventricles.

The spread of impulses over the ventricles, if activation occurs by way of an accessory pathway, may logically be considered more comparable to ventricular ectopic beats than to bundle-branch block. The literature immediately available contained no information on the pattern of precordial leads during ventricular ectopic beats. Accordingly, multiple chest leads were obtained in patients with frequent ventricular ectopic beats. The result in one such case—that of a twenty-five-year-old Negro with trigeminal rhythm but no detectable heart disease—is shown in Figure 2. It may be seen that the pattern is the same as in left bundle-branch block. Over the right ventricle the onset of the intrinsic deflection in the ectopic beat is delayed for only 0.04 second—0.02 second more than for the normal beats in the same area. Over the left side of the precordium the onset of the in-

was available at all times in the bleeding room. In addition, all donors with syncope were seen by the medical officer in charge, and in each case a report stating the time of onset and giving various other data pertaining to the reaction was immediately made out. The pulse and blood pressure were taken at five-minute intervals and recorded until normal levels were obtained.

CLASSIFICATION OF SYNCOPE

Syncope is a transient form of vasomotor collapse that has certain characteristic symptoms and signs. Although various classifications have been proposed for syncope in blood donors,³ reactions that did not require additional rest were disregarded in this study. Those in which there occurred loss of consciousness or convulsive manifestations were arbitrarily classified as severe syncope, otherwise the case was classified as mild syncope. In this manner 162 cases of syncope were encountered in the first series, 17 of which were severe, and 527 cases in the second series, 158 of which were severe.

On the basis of this experience an attempt has been made to present the clinical findings and to discuss the constitutional and contributory factors in syncope. Since the 158 cases of severe syncope in the second series were the best defined and most accurately controlled, more detailed observations are presented in regard to them than in regard to those in the first series.

CLINICAL MANIFESTATIONS

The symptoms and signs of syncope encountered in this study were similar to those described in blood donors by Brown and McCormack.⁴

Symptoms

Syncope often developed without warning, but some donors complained of weakness or dizziness, and at times restlessness, yawning or sighing occurred. Rarely a definite aura was present. The most frequent symptom with the attack in the 158 severe cases in the second series was a feeling

TABLE I Physical Signs of Severe Syncope

of warmth, which occurred in 63 per cent. Epigastric distress (32 per cent) and nausea (32 per cent) were also present but were usually mild in degree. In addition, there were a variety of other less frequent complaints, such as spots before the eyes, blindness, tinnitus, urgency to void or defecate and numbness and tingling in the hands.

Signs

The nature and frequency of the various physical signs of severe syncope are shown in Table I.

Pallor This was the most frequent sign and was usually marked. At times the skin showed a cyanotic tinge, and in some of the more profound cases the patient gave the appearance of impending death.

Loss of consciousness The onset was usually abrupt. Most donors remained unconscious for only a few seconds, but in some unconsciousness was more prolonged. Consciousness was generally recovered suddenly, and there was amnesia for the event.

Fall in pulse Of the 158 donors with severe syncope, 83 per cent had a pulse of 60 or lower. In a control group 45 per cent of donors had a pulse of 60 or below after bleeding. In cases of extremely severe syncope the pulse was frequently imperceptible or very slow.

Fall in blood pressure Seventy-seven per cent of the donors with severe syncope had a drop in systolic blood pressure of 30 or more, compared with 1 per cent in a control group. There was always a concomitant and corresponding drop in the diastolic pressure. The lowest blood-pressure level was usually the initial one, and this did not necessarily occur during the period of unconsciousness. The blood pressure generally rose during the recovery period, which in most cases was half an hour or less, but occasionally the low blood pressure persisted for hours.

Sweating This was a frequent finding. Drenching perspiration was observed more frequently in men, especially in those with profound syncope. Sweating occurred all over the body, but unlike this sign in traumatic shock, the skin was usually warm rather than cold.

Dilatation of pupils Pupillary changes were found in over a third of the cases of severe syncope. These were of variable degree and often so transient that they may have been missed in some patients. Occasionally the pupils were constricted, but no definite correlation between either type of pupillary changes and the degree of syncope was noted.

Generalized convulsions In donors who had convulsive seizures the onset was almost always abrupt. A tonic spasm was usually present throughout the body, and frequently the head and eyes deviated to one side, with the back arched in opisthotonos. The pupils were generally dilated and momentarily fixed. In some cases there were clonic movements of the extremities, followed by a period of snorting, stertorous respiration. The face was usually flushed and occasionally slightly cyanotic. The blood pressure during the attack was normal or slightly elevated. Immediately afterward in some donors a drop in blood pressure and pulse was observed, but in others there was no fall in blood pressure or pulse, either during or after a

the auricle and ventricle does not satisfactorily account for some of the characteristics of the syndrome. In particular, it does not seem to explain observations made with multiple chest leads.

Since this manuscript was submitted, a comprehensive study of precordial, thoracic and esophageal leads in the Wolff-Parkinson-White syndrome has been reported by Rosenbaum et al.⁶ They suggest that when the anomalous pattern is present, conduction occurs by way of both the normal conduction pathways and one or more accessory pathways. Although this suggestion helps to explain the pattern better than does the theory of aberrant spread throughout the ventricles, the hypothesis rests on a good deal of speculation. It is logical speculation, however, and tempts one to conjecture that the premature excitation involves a particular muscle bundle—probably one of the deeper ones. The reasons for such a conjecture are as follows. First, the magnitude of the premature component of the QRS complex suggests that a sizable bulk of muscle is involved. Second, if one assumes that the onset of the intrinsic deflection signals the arrival of the impulse at the epicardial surface underlying the electrode, it follows from the study of unipolar leads

that the premature excitation does not reach the epicardial surface at any point that can be reached by indirect unipolar leads.

SYNCOPE IN BLOOD DONORS

MAJOR WILLIAM C. MOLONEY, M.C., A.U.S.,* CAPTAIN LELIAS R. LONNERGAN, M.C., A.U.S.

AND MAJOR JAMES K. MCCLINTOCK, M.C., A.U.S.

THE present emergency has provided an unusually abundant opportunity for the study of syncope, or fainting, in blood donors. Although not in itself serious, fainting results in loss of time to the donor, it is detrimental to the efficiency of the donor center, and, as pointed out by Taylor,¹ an occasional donor has fallen and suffered injury. The present investigation of some of the clinical and etiologic aspects of syncope was undertaken to aid in reducing the incidence of fainting in blood donors. Aside from practical considerations, it is hoped that the observations and data recorded in this paper will shed some light on the pathogenesis of the complex and interesting problem of syncope, about which, as McDowell² has recently stated, there exists a great deal of confusion.

MATERIAL AND METHODS

This study concerns two series of blood donors bled under different circumstances and therefore offering some interesting comparative data. The first series consisted of 6882 donors—2202 men and 4680 women—who were bled between May, 1942, and March, 1943. The blood was obtained at the Atlanta Red Cross Blood Donor Center under the direction of the Blood Research and Plasma Laboratory of the United States Army. Physically fit donors were selected on a basis similar to that of the present Red Cross requirements, with certain important variations. A donation could be either 250 or 500 cc, but no 500-cc donations

were taken from persons under twenty-one years of age or weighing less than 150 pounds. If a donor was nervous or if other reasons seemed to warrant it, only 250 cc was taken even if the donor was within the weight and age limits of the larger donation. All the bleedings were done by the staff of physicians assigned to the center, and a closed-vacuum-bottle method was employed. The donations amounted to only thirty to seventy a day, so that it was possible to adopt an unhurried attitude and to permit the donor to rest for ten or fifteen minutes on the bleeding bed after the donation. The second series consisted of 9251 donors—3917 men and 5334 women. Bleedings were taken from March 8 to June 1, 1943. This program was carried out according to the methods and techniques recommended for use in Red Cross blood procurement centers.¹ All accepted donors weighing 110 pounds or over gave 500 cc of blood, unless, as in exceptional cases, the bleeding had to be stopped before this amount was obtained. The techniques of the preparation of the arm and the venipuncture were the same in both series, but in the second series the standard Red Cross bleeding set¹ was used, and practically all the bleedings were done by specially trained graduate nurses. One or two staff physicians were in charge of the bleeding room at all times. Of necessity, the atmosphere was somewhat more impersonal than in the first series, moreover, the rest after bleeding was shortened to five minutes unless otherwise indicated.

The personnel was instructed regarding the early signs and symptoms of syncope, and a trained nurse especially designated as the "reaction nurse"

hardly significant figure. In the present study the surface area of donors in severe syncope differed little from that of controls, this was true of both sexes (Table 2).

In experiments with professional donors, Ebert, Stead and Gibson⁹ found that if 15 to 20 per cent of the normal blood volume was removed collapse

TABLE 2 Surface Area and Blood Volume in Control Donors and Those with Severe Syncope

DONORS	SEX	NO OF DONORS	AVERAGE SURFACE AREA	AVERAGE BLOOD VOLUME
			sq m	cc
Control donors	F	114	1.66	4980
	M	78	1.91	5750
Donors with severe syncope*	F	88	1.65	4950
	M	67	1.86	5580

*Three cases omitted because of incomplete data

usually ensued and that this state had all the features of syncope. These authors also emphasized the role of psychic and reflex factors in collapse. In obtaining blood under the conditions outlined in this paper, however, even the donor with the smallest blood volume did not lose more than 12 per cent of his blood. Nevertheless, it seems logical to assume that a person deprived of a relatively greater percentage of blood will be less capable of adjusting the circulatory mechanism in the presence of reflex vasomotor change than those deprived of smaller amounts.

Environment. The importance of the surroundings and the attitude of the staff in the donor center has been emphasized by Williams¹⁰ and Taylor.¹ Undoubtedly in this study the more favorable circumstances under which the first series of donors was bled contributed materially in lessening the syncope rate as compared with that in the second series.

Occupation. Fatigue, lack of sleep and dehydration due to heavy or prolonged occupations are no doubt factors in syncope.⁸ Such conditions were not encountered in this study. Greenbury³ found that young female clerical workers fainted oftener

TABLE 3 Contributory Factors in Severe Syncope

FACTOR	CONTROL DONORS	PERCENTAGE DONORS WITH SEVERE SYNCOPE
History of fainting	16	50
Nervousness	23	49
Fatigue	15	33
Fasting for over five hours	53	65
Pain from venipuncture	7	11
Donation		
First	64	67
Second	22	11
Third or higher	14	3

than did those in other occupations, but he did not take into account age and other factors, which appear to have much more bearing on the problem than does occupation.

Weather. It is a widespread belief that fainting occurs with special frequency in a warm atmosphere, but studies by various authors tend to discount

the influence of high humidity and temperature. An investigation of these factors was carried out in this study. Although no close correlation was evident, the impression gained from clinical experience that heat and humidity contribute to higher syncope rates persists.

CONTRIBUTORY FACTORS

In addition to the constitutional and general factors, there are a number of important contributory factors in syncope. Some of these are shown in Table 3, which is a comparison of a group of 200 control donors with those in the second series who had severe syncope. An outstanding fact was the high incidence of a prior history of fainting in the syncope group as compared with that in the controls. It is also apparent that nervousness and fatigue play important roles in conditioning a person to fainting. Since fasting was common to both groups, it is difficult to evaluate. Lawrence and Plaut¹¹ found no significant difference in blood-sugar levels between fainters and non-fainters, and hypoglycemia probably does not enter into the picture. Pain is a relatively infrequent complaint owing to the use of local anesthesia and skillful venipuncture, and hence has not been a significant factor in syncope.

When severe syncope occurred on the first donation, the donor was not called back for further donations. Nevertheless, since nervousness and apprehension are much more evident on the first visit to the donor center than at later ones, the high incidence of severe syncope on this occasion as compared with the much less frequent occurrence on subsequent donations is understandable.

Epidemic Fainting.¹² This phenomenon was encountered not infrequently in young donors. These persons, usually from the same office or service group, would "talk each other into a faint." Promptly placing the donor in a supine position almost always resulted in a mild type of syncope, the *forme fruste* of Weiss.¹² Epidemic fainting is excellent evidence of the strong psychologic effect of suggestion.

Postural Factors. As pointed out by Weiss,¹² syncope usually occurs in the upright position. Nevertheless, in these blood donors severe syncope frequently developed in the supine position. This finding must be qualified by the fact that some delayed faintings were not reported, especially if the donor had left the center. Second, in a number of patients with mild or incipient syncope this would have undoubtedly become severe if they had been allowed to get up before the circulatory system had become adjusted. It is evident that a change in posture may bring about increased cerebral ischemia and act as a contributory factor to precipitate syncope.

DISCUSSION

The clinical features of syncope as observed in this study were quite similar to those described by

convulsion All these donors were apparently unconscious during the seizure, but none of them bit their tongues or sustained any significant injury, even with violent convulsions

Vomiting Although relatively infrequent, vomiting was occasionally severe and profuse Many donors felt relieved after it, but in some cases nausea and epigastric distress persisted for hours Vomiting may be an outstanding feature of otherwise mild cases of syncope

Loss of sphincter control Although of rare occurrence, urinary incontinence was observed, especially in young women It was invariably associated with deep syncope and often occurred during or just following a convulsive seizure Loss of bowel control was not observed, but a few donors experienced an urgent desire to defecate

Hyperventilation and tetany Various respiratory changes, such as slow, rapid, deep, shallow and intermittent breathing, were observed Of these, hyperventilation was the outstanding finding Following it the typical symptoms and signs of tetany were observed in 6 cases, with carpopedal spasm, a positive Chvostek sign and numbness, tingling and

investigators, however, and it is generally accepted that overbreathing in nervous persons with subsequent loss of carbon dioxide, causing a change in pH of the blood bathing the cerebral centers, is the most logical explanation of hyperventilation tetany^{6, 7}

CONSTITUTIONAL AND GENERAL FACTORS

Age and sex Young donors are much likelier to faint than are older ones Although 75 per cent of the cases of severe syncope occurred in donors between eighteen and thirty-eight years old, this age group comprised only 58 per cent of the total donors (Fig 1) There was little difference between the syncope rates in men and those in women On closer analysis, however, it becomes apparent that young women faint much oftener than any other group of donors As shown in Figure 2, 47 per cent of the women de-

FIGURE 1 Relation of Age to Syncope

pain in the jaw and extremities One of these donors also presented evidence of syncope, although she did not lose consciousness

Tetany may occur without syncope, but tetany, convulsions and syncope may all occur in the same person Frazer and Forweather⁸ recently described 7 cases of tetany in blood donors, in some of which there was a fall in blood inorganic phosphorus This finding has not been confirmed by other in-

FIGURE 2 Relation of Age and Sex to Syncope

veloping severe syncope were between the ages of eighteen and thirty-eight, as compared with 29 per cent of the men

It is also interesting that in the few young women included in the first series the syncope rate was 3 per cent, whereas in the second series, with many more young woman donors, it was 5 per cent

Surface Area (Blood Volume) and Amount of Blood Withdrawn It is generally believed that the amount of blood loss is an outstanding factor in the production of syncope in donors If this is true, there should be a relation between blood volume and syncope, provided that the amount of blood withdrawn is constant Poles and Boycott⁹ found that the body surface of fainters was lower than that of non-fainters, but if it is accepted that approximately 1 square meter of body surface is equivalent to 3000 cc of blood, the difference in both sexes between syncope and control cases in the Poles and Boycott series amounted to an average of only 0.06 square meter or 180 cc of blood, a

ELECTROENCEPHALOGRAPHIC STUDIES IN DIABETES MELLITUS*

MILTON GREENBLATT, M D,† JEAN MURRAY, M D, AND HOWARD F ROOT, M D ‡

BOSTON

ELECTROENCEPHALOGRAPHIC studies have become an almost routine procedure at the New England Deaconess Hospital in examining diabetic patients who have frequent insulin reactions or seizures in which hypoglycemia is considered a possible precipitating factor. Although the incidence of epilepsy among diabetic patients has not proved to be greater than that in unselected persons of corresponding age groups, the occurrence of repeated insulin reactions in a specific case always raises the question whether they are due to an abnormally rapid change in the blood sugar or to instability of the nervous mechanism — that is, to an epileptoid tendency. The electroencephalogram was therefore invoked as an aid in studying the cortical activity of patients with diabetes mellitus to establish or rule out the existence of epilepsy.

It is known that diabetic patients are more sensitive to hypoglycemia than are persons with a normal carbohydrate metabolism — a fact that Root et al.¹ have recently demonstrated in their studies of radioactive insulin and its absorption. They examined normal controls and diabetic patients given identical doses — 25 units of crystalline insulin — and found that all the latter patients developed hypoglycemic reactions, as compared to only 1 of the controls.

In experiments on normal persons the brain waves are progressively slowed by a reduction of the blood-sugar level to below 50 to 60 mg per 100 cc, and this slowing is readily correlated with outward clinical manifestations.^{2,3} The reduction of blood sugar in normal persons by means of insulin given for short periods of time produces no irreversible effects in the electroencephalogram. Injection of sugar restores the brain-wave frequency along a smooth curve.

It is not known whether repeated insulin reactions or hypoglycemic spells can eventually produce abnormal cerebral electrical activity. It will be shown, however, that in diabetic patients subject to repeated severe insulin reactions a startling degree of electroencephalographic abnormality exists. This may be due to inherent instability of the nervous system, to repeated deprivation of essential brain foodstuffs during hypoglycemia or to recurrent cerebral edema and minute petechial hemorrhages sustained during periods of profound hypoglycemia.

Himwich⁴ has shown that profound hypoglycemia may depress the brain metabolism to one quarter of its normal rate. He mentions that a late and prolonged stage of hypoglycemia may produce permanent brain damage. Gellhorn and Kessler,⁵ studying insulin-sensitive rats, found that insulin hypoglycemia produced the same type of effect on the electroencephalogram as that seen with anoxia.

Concerning nondiabetic epileptic patients, the evidence as presented by Gibbs et al.⁶ is that a low blood-sugar level may increase the electrical abnormality in patients with petit mal, but does not do so in patients with grand mal or psychomotor epilepsy.

TECHNIC

A Grass six-channel electroencephalogram with undistorted recording up to 50 cycles a second was used. Electrodes were applied to the frontal, parietal and occipital areas. Recordings were done in a darkened room with the patient's eyes closed. In all control subjects the blood-sugar level was determined shortly before the test. A two-minute period of overbreathing was included in every test. The records were classified as normal, borderline and abnormal, on the basis of experience with several thousand patients with and without neuropsychiatric disturbances.

RESULTS

Patients with Uncomplicated Diabetes

A group of 40 patients with uncomplicated diabetes served as controls for 35 diabetic patients with repeated severe insulin reactions. The ages of the controls ranged from eighteen to forty-nine years with an average of thirty-four years. In this range one can expect the least number of variations in brain activity caused by immaturity or by senile changes. The previous duration of diabetes was one week to twenty-one years, and 20 patients had had the disease for ten years or more. The blood-sugar levels before the electroencephalographic examination ranged from 116 to 428 mg per 100 cc. All the patients were ambulatory and in good health. None of them had a history of seizures, personality change or neurologic disturbance. All patients but 1 were taking insulin, in doses ranging from 10 units of protamine-zinc insulin to 26 units of crystalline insulin and 76 units of protamine-zinc insulin.

The records were classified as within normal limits in 32 cases, as borderline in 5, and as distinctly abnormal in 3. Analysis of these three groups revealed no significant differences in age, sex, duration of diabetes, duration of insulin intake or type of in-

Lewis¹⁸ and Weiss^{12, 14} and to those observed more recently in blood donors by several British writers^{4, 8}

It is evident that certain constitutional and contributory factors influence the production of syncope in blood donors. The young donors, especially women, were those most prone to fainting, and as suggested by Williams,¹⁰ this may be due to an increased vasomotor instability in younger persons. It has been pointed out that in blood donors syncope differs from the usual form of fainting in that it frequently occurs with the donor in the supine position and usually develops following withdrawal of 500 cc of blood. Nevertheless, in this series syncope occurred without loss of blood and with the donor lying down, the attack simulating in every detail that occurring after withdrawal of blood. It seems obvious that although blood loss and posture may be important conditioning factors, they are not the *sine qua non* of syncope.

The physiologic mechanism of syncope is obscure, but its various and puzzling manifestations undoubtedly occur as a result of a number of reflex stimuli passing along both sympathetic and parasympathetic pathways. Recent studies by McMichael¹⁵ indicate that in vasovagal collapse the fall in peripheral resistance is due to reflex dilatation of the arterioles in the skeletal muscles. It is evident that the work of McDowell² and other British investigators¹⁶ will go far toward dispelling the obscurity surrounding the vasomotor and cardiovascular phenomena associated with syncope.

TREATMENT

Syncope may give rise to alarming symptoms, and in severe cases the patient may assume a death-like appearance. Indeed, in some cases it is impossible to detect a radial pulse or to obtain the blood pressure for several minutes. There is no doubt that such a severe vasomotor collapse could precipitate serious trouble in subjects with latent or potential organic cardiovascular disease. For this reason the elimination of those subject to fainting is an important consideration. In common with recent British opinion,¹⁷ it is believed that donors with a history of prior fainting should be rejected as candidates for blood donation. The high incidence of a history of easy fainting—50 per cent of the cases of severe syncope in this investigation—has been noted by others.^{10, 17} The use of donors who are excessively tired or nervous should also be avoided, and psychic factors should be eliminated in so far as possible.

For the immediate treatment of fainting the most effective measure is to place the patient in a supine position with the lower extremities elevated. It is

important to keep him at rest until the blood pressure has returned to normal levels to prevent re-collapse, which sometimes occurs after the donor has left the center, with subsequent fall and injury. The use of vasoconstrictor drugs such as N-methylamphetamine, as noted by McMichael,¹⁵ may well be employed in severe cases of syncope.

SUMMARY AND CONCLUSIONS

In an experience with 16,133 blood donors, 689 cases of syncope were encountered, an incidence of 4.2 per cent.

Detailed observations on the symptoms and signs of severe syncope are recorded. Although these were often dramatic, in no case in this series were there any serious sequelae.

The frequent history of prior fainting in a series of cases of severe syncope is especially noteworthy, and the importance of psychogenic factors in syncope is emphasized.

Recent studies give promise of furnishing new insight into the complex physiologic mechanism involved in syncope, but there is much that remains obscure. The following statement of Gowers, quoted by Weiss,¹² seems as true today as it was in 1907: "Familiar as fainting is, adequately as we seem to know it, there is much in it that we do not know. Our knowledge is enough to obscure our ignorance."

nificant fraction of cases present extreme difficulty in control by routine methods, and require special attention. These patients are inordinately sensitive to relatively minor changes in the blood-sugar level, and their clinical reactions are disproportionately severe. The manifestations of insulin sensitivity are highly variable.

In cases of this kind it is of both theoretical and practical importance to know what role the nervous mechanism plays in the fundamental instability. Because the changes primarily involve carbohydrates, the chief foodstuff of the brain, one is naturally inclined to suspect disordered function within the central nervous system. From the clinical point of view, many of the reactions involve abnormal but co-ordinated motor manifestations or specifically suggest epilepsy. Other reaction patterns such as unconsciousness, point incontrovertibly to abnormal cerebral function.

The electroencephalographic evidence supports the theory that severe repeated insulin reactions are due not only to unstable carbohydrate regulation but also to unstable cerebral, and specifically cortical, function as well. Some of the electroencephalograms obtained were indistinguishable from interval patterns in patients suffering from grand-mal epilepsy. The incidence of abnormal or atypical brain wave tracings in the unstable group of diabetic patients is too high to be due merely to chance.

The observations established the fact that the central nervous system plays a leading role in the instability of patients with so-called "problem diabetes" or diabetes regulated with great difficulty. In this group the possibility of cortical instability should never be neglected in evaluating the functional difficulties of the patient, and by implication, proper treatment should encompass proper management of the central-nervous-system disorder. The electroencephalogram may be invoked as a valuable aid in

studying diabetic patients with frequent severe insulin reactions.

SUMMARY

In a study of 40 patients with uncomplicated diabetes, the incidence of cerebral dysrhythmia as evidenced by abnormal electroencephalograms is not increased over that in normal persons.

Long duration of diabetes does not alter the incidence of cerebral dysrhythmia.

Administration of insulin over long periods of time has no apparent effect on the electroencephalograms.

Fifty-one per cent of diabetic patients with frequent severe insulin reactions were found to have abnormal electroencephalograms.

The electroencephalograms are of aid in the evaluation of the stability of cortical function in diabetic patients with such reactions.

sulin used The following is a brief summary of the controls with definitely abnormal electroencephalograms

CASE 1 (No 22895) A 47-year-old woman had been taking insulin since the onset of diabetes in 1929 The dosage at the time of the electroencephalographic study was 4 units of crystalline insulin and 26 units of protamine-zinc insulin On the maximum dose of 8 and 36 units, respectively, there were several mild reactions, with blood-sugar levels of 44 and 46 mg per 100 cc, but no convulsions or unconsciousness

CASE 2 (No 13831) A 47-year-old woman had had diabetes for 9 years Insulin had been given since 1935 At the time of the electroencephalogram she was receiving 28 units of crystalline insulin and 58 units of protamine-zinc insulin, which was the maximum dose She had a basal metabolic rate of +30 per cent, with toxic adenoma of the thyroid gland, which was later removed The electroencephalographic abnormality may have been related to the cerebral electrical disturbance of hyperthyroidism

CASE 3 (No 7336) A 43-year-old man, with diabetes of 15 years' duration, had taken insulin for the entire period, the dosage being 4 units of crystalline insulin and 20 units of protamine-zinc insulin The blood-sugar level at the time of the examination was 428 mg per 100 cc There had been a recent severe insulin reaction, with unconsciousness but no convulsions Insufficient insulin was taken by the patient because of fear of recurrence At a subsequent office visit he was ambulatory, with a blood-sugar level of 44 mg

These 3 patients comprise 8 per cent of the entire control group studied, which compares favorably with the incidence of cerebral dysrhythmia of 8 to 10 per cent in general unselected groups of non-diabetic persons Lennox states, "It is important to realize that even though certain individuals, probably about 10 per cent of the population, have a cerebral dysrhythmia and, therefore, presumably carry a predisposition to seizure or allied conditions, such seizures or conditions may never eventuate unless one or more of the other causes of seizure are present"

In essentially uncomplicated diabetes of long duration, the figures for electroencephalographic abnormality are quite similar to those in uncomplicated diabetes of short duration Of the 20 patients with a long duration, — ten or more years, — 2 had abnormal electroencephalograms In 10 patients, the onset of diabetes had occurred before the age of fifteen years No one of these cases was recorded in the abnormal class, 2 were in the borderline group, and the other 8 were normal This may be of interest because of the increased incidence of epilepsy in diabetic children, in whom it is 1.07 per cent, as compared with 0.84 per cent in normal children⁸ All classified as child diabetic patients have relatively severe diabetes and have taken insulin for a minimum of approximately fifteen years

Diabetic Patients with Repeated Severe Insulin Reactions

Thirty-five diabetic patients with repeated severe insulin reactions — problem cases — were also evaluated from the electroencephalographic point of view The clinical manifestations of these attacks included dizziness, weak spells, transient disturb-

ances of memory, aphasia or paresis, temper tantrums, attacks of petit mal, convulsive attacks and spells of unconsciousness In some cases hypoglycemia was known to be present and improvement occurred with the administration of carbohydrate All patients were studied between attacks, when they had no clinical symptoms of hypoglycemia

The ages varied from fourteen to fifty-four years with an average of 25.7 years The duration of diabetes ranged from 5 months to twenty years, with an average of 8.2 years Blood-sugar levels were not ascertained in all cases before the electroencephalographic tracings, but no patient had clinical symptoms of hypoglycemia at the time they were made All the patients were taking insulin in doses ranging from 8 crystalline and 16 protamine-zinc units to 36 crystalline and 78 protamine-zinc insulin units

The tracings were classified as normal in 8 cases, as borderline in 9, and as definitely abnormal in 18 There was no significant difference between these three groups in age, duration of diabetes, duration of insulin intake or type of insulin taken The types of insulin reaction in all groups were quite varied

DISCUSSION

Diabetic patients in general do not suffer from epileptic phenomena more than do members of a normal group Similarly, electroencephalograms in cases of uncomplicated diabetes are essentially

FIGURE 1 Percentage of Normal, Borderline and Abnormal Electroencephalograms in 40 Control Diabetic Patients and in 35 "Problem" Diabetic Patients

The blank blocks represent the control group, and the cross-hatched blocks the "problem" group

within normal limits This is true irrespective of the duration of diabetes, the duration of insulin treatment or the amount of insulin administered In clinics in which large groups of diabetic patients are studied, however, a small but nevertheless sig-

tween 1910 and 1915. There is now the pressure behind disability compensation. The original concept of workmen's compensation was one of weekly cash payments during the period of disability. This concept is held with respect to disability compensation. Soon after the initiation of workmen's compensation, the fact that people were not using their weekly payments to purchase necessary medical care became evident. It also became evident that the provision of medical care would "pay dividends." Hence, medical services were introduced as a part of workmen's compensation; the services have steadily increased, and today any proposal to exclude such services would be regarded as contrary to sound policy. The parallel presents itself in disability compensation. It will be interesting to see how long such a system as that in Rhode Island operates without medical services as a part of the scheme.

There are many questions that involve the combination of independent group practice and group payment. Here, too, the administrator thinks in terms of practical application. The qualitative values of group practice are seldom questioned, but within the group, recognition must be given to certain essentials: the income for each member must be reasonably adequate, and his tenure as a member of the group must be reasonably stable. Assuming that a group is organized to serve 50,000 people on a voluntary prepayment basis, the population must be one whose income is stable. Thus, it cannot be one of 50,000 today and one of 30,000 a year later owing to unemployment. A medical group dependent for its stability on a continuing income and having a staff large enough to care for 50,000 people might weather a short-term decrease to 30,000, but it could not weather a long-term one. It is for this reason that the most successful medical group practice under a system of voluntary prepayment is the one that includes that small portion of the population with stable incomes — policemen, firemen, schoolteachers and others with annual salaries. To include industrial populations with extremely fluctuating levels of employment means that the medical group must face the difficult problem of preparing against abrupt decreases in income. If this preparation is inadequate or impossible and the emergency comes, the group is threatened with disintegration.

Mention has been made of voluntary prepayment. The question of compulsion *versus* volition is presented as one of the sharpest issues of the day. But it is not really so sharp as it has been drawn. There are many forms of compulsion other than legal. There is the pressure of sales, the pressure of group or public opinion, the moral pressure of employers on employees and the even greater pressure exerted by employer contributions as partial payment. Actually, the issue is becoming less and less one of compulsion *versus* volition and more and more one of legal compulsion *versus* quasi-compulsion.

There is another broad generalization that calls for much more critical examination. It has to do with the method of compensation for services, from the administrative standpoint it causes apprehension. The evidence is fairly clear that, whatever the future prepayment plan for medical care, it will begin with fees for specified services as the method of compensation to physicians. There may be changes to so-called "capitation fees" or ultimately to salaried services, but the administrator must deal with immediate problems, not with ultimate possibilities.

The fee-for-service method of payment has a long and broad history of failure. It is unlikely that it will work merely because of resolutions that describe it in flattering terms and declare it to be "the American way." Not only did it fail yesterday but it is failing today. Even though an appendectomy rate of 25 per 1000 subscribers, for example, does not endanger the economic foundation of a prepayment plan, such a rate is approximately triple the normal one and points to a need for administrative action; absence of action means another failure for the system. "Control" is a hated word, but the application of necessary and fair control measures is not nearly so dangerous as is the continued evasion of brutal facts. The fee-for-service method if applied with all the ingenuity of which administrations are capable might be made to work, applied without such ingenuity it has in it the elements of a national calamity.

The final example of administrative problems in prepayment programs relates to the two major forms of the benefits to subscribers. In one case the subscriber's contract calls for services, in the other, the benefits are distributed in cash. In the first case, the subscriber would receive an appendectomy and the surgeon would be compensated directly from the fund, probably receiving \$100 as full payment for the service. In the second case, when the subscriber presents written evidence that an appendectomy has been performed, the company or the plan indemnifies him, a check being sent either to him or directly to the surgeon.

All this appears to be six of one and half a dozen of the other. Whereas the great majority of the voluntary plans provide services, the insurance company plans indemnify in cash. It is the recommendation of many medical societies that the principle of cash indemnity be applied, yet if the principle is widely applied, it is doubtful that it can withstand the accumulative weight of public disfavor.

As an insurance device, cash indemnity as now used is unsound. The subscriber purchases in good faith what he interprets as protection, but not until the contingency arises is he able to learn the degree of his protection. It may be 100 per cent or 50 per cent, depending on the charge for the service. No other form of insurance could exist if this principle

SYMPOSIUM ON MEDICAL SOCIOLOGY

MEDICAL ECONOMICS*

NATHAN SINAI, D P H †

THE title of this lecture is actually the inclusive title of the entire series. The series can serve only to provide a superficial view of the issues involved. If out of this view there emerges a continuing and critical analysis, the series will have had high value. If, on the other hand, the series ends with final decisions on the part of the audience, it must be concluded either that these decisions were brought to the meetings or that the speakers were highly persuasive.

In arriving at conclusions, there is an acute need throughout the country for the tested device that is such a common procedure in medicine—the device embraced in the words “examination, diagnosis, treatment.” The fallacy of centering attention on treatment without any agreement concerning diagnosis, which, in turn, is based on a critical examination, is obvious. It is so obvious that one wonders at its prevalence. Because of this prevalence, about two thirds of the courses in this field for sophomore and senior medical students at the University of Michigan are purposely devoted to “examination and diagnosis.”

There is one aspect of medical economics to which attention has been pitifully inadequate. Most of the discussions in the country have revolved around broad principles, broad philosophies, broad plans and broad legislation. Their very breadth excites passionate debate, but ultimately, whatever principles, philosophies, plans or legislation are adopted, these must be transformed into the realities and details of administration. So far, this fact has almost entirely escaped attention. Because of this, and in spite of the discussion, the average physician is unable to see himself and his concept of practice within the framework of any scheme that may be proposed. What are needed are fewer panoramas and many more “closeups.” Some of the problems and situations that administrators must face within the framework of various broad proposals are the following:

The statement is generally accepted that the public wants and needs medical protection against so-called “catastrophic illness,” but there is a tendency to leap from this to the conclusion that practically all medicoeconomic catastrophes involve the

hospital and either the surgeon or the obstetrician. It is said that 10 per cent of the people pay 41 per cent of the total medical bill, the hospital, the surgeon and the obstetrician being the chief payees. But a few other facts and diagrams insist on obtruding themselves, and the word “catastrophe” then becomes less easy to define in terms of absolute costs. Indeed, it becomes a relative matter closely linked to the income groups in the country.

It will be recalled that the Wagner-Murray-Dingell Bill proposes to exclude the services of dentists. The decision to exclude them was probably based on the knowledge of the overwhelming number of existing dental defects and the lack of enough dentists to cope with the problem as a whole. Practically all those who questioned the exclusion thought in terms of at least a partial attack on the problems, especially with respect to the needs of children, but from the administrative standpoint, the exclusion raised an entirely different question.

In many parts of the country a large portion of the oral surgery is performed by specialists whose training and professional degrees are in dentistry. They are the ones who provide services in such cases as jaw fractures. If the exclusion of dentists had been adopted, the bill would have created an anomalous situation in which the services would have been included, but the many specialists who provide them would have been excluded. It is not intended to imply that this was the intention of the authors of the bill, the statement is only one of what would have happened in its administration.

To the administrator, the role of medical care as a buttress for other systems of security is a weighty one. It is estimated that by the end of the next thirty years persons above the age of sixty will comprise almost a fifth of the population. Only a cursory examination of the curve of illness according to age is necessary to reach the conclusion that old-age annuities cannot provide protection against the concentration of illness in the upper age groups. The same general conclusion is warranted as concerns unemployment payments under a system of unemployment insurance.

On the subject of security, another movement taking place in the country deserves much more attention. It is the movement toward disability compensation. There is danger in reasoning by exact analogy, but the only greater danger lies in discarding all previous experience. Workmen's compensation legislation swept the country be-

*This is the fourth of a series of nine lectures on medical sociology given weekly at Harvard Medical School during January, February and March, 1945. They were sponsored by the Department of Preventive Medicine and were primarily intended for third year students. These articles will temporarily replace the reports “Medical Progress.”

CASE 32041

PRESENTATION OF CASE

A twenty-nine-year-old clerk entered the hospital complaining of recurrent pain in the flanks.

Eight years before admission he had an attack of sharp pain in the right flank, and later passed several stones by urethra, followed by slight bleeding, which lasted for thirty hours. Another stone was passed two years later, and on chemical analysis was found to consist of calcium phosphate. A third attack of pain in the right flank and passage of stones occurred three years before admission, while in the Army. Similar episodes recurred four and eight months later. The sixth passage of stones took place eight months before admission, at that time another stone was detected by x-ray examination in the right renal pelvis and a right nephrolithotomy was performed. Several weeks later, pain was noticed in the left flank for the first time and stones were again passed. The patient was later discharged from the Army.

Weakness and fatigue had not been marked. For three years, however, the patient had not been able to resume the upright position after leaning over. No polyuria, frequency or evidence of renal infection had been noted. The appetite had been good, and he had complained of no bone pain. Four years before admission he had sustained a traumatic fracture of the left fifth metacarpal, healing was normal. The teeth had been in good condition. His maximum weight had been 140 pounds, three years before admission, at the time of admission his weight was 120 pounds, with no recent loss.

Physical examination revealed a thin, pale man in no discomfort. The pharynx was moderately injected, with a postnasal drip. The teeth were normal. The trachea was slightly deviated to the left, with a questionable soft-tissue fullness on the left. The heart was not enlarged. A soft systolic murmur was heard over the apex. The lungs were clear. There was no costovertebral-angle tenderness. The bones were normal. Neurologic examination was negative.

The temperature was 99.2°F, the pulse 80, and the respirations 20. The blood pressure was 130 systolic, 75 diastolic.

The hemoglobin was 14.7 gm. The urine contained an occasional white cell, mucin and calcium oxalate crystals. A twenty-four-hour urine specimen, which had a volume of 1688 cc., contained a total of 288 mg. of calcium. The serum calcium was 10.7 mg. per 100 cc., the phosphorus 3.0 mg., and the alkaline phosphatase 4.0 Bodansky units. Determinations the next day were as follows: serum calcium 10.7 mg. per 100 cc., phosphorus 3.1 mg., and alkaline phosphatase 4.9 units. The total serum protein was 6.0 gm. per 100 cc. A blood Hinton test was negative.

An x-ray film of the teeth showed no parodontal disease, the lamina dura was preserved but of unusual thickness. The bones of the jaw were not so dense as usual, and the trabeculae were coarse. The bones of the lumbar spine and pelvis, the upper portions of the femurs and the lower ribs showed some decalcification, the cortices were thinned, and the trabeculae coarse. No urinary calculi were evident. Several areas of increased density overlay the cecum.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. ALLAN M. BUTLER: Either the clinicians who took care of this patient were extremely wise or they had more data than those given in this abstract on which to base the decision to perform an operation. We have no information about renal function. We have only the statement that no evidence of renal infection was found on one examination. There was no intravenous pyelogram, and no determination of the serum carbon dioxide and chloride. Is that correct?

DR. BENJAMIN CASTLEMAN: We have given you all the information that was in the record.

DR. BUTLER: Then I must confess that, not being so intelligent as the physicians who took care of this patient, I should have demanded that information before doing an operation.

We shall now consider the x-ray films. I wish that we had a roentgenologist to interpret them, for I see nothing suggesting why this man was unable to resume the upright position after leaning over. Do you see anything in the films, Dr. Aub, that would cause this?

DR. JOSEPH C. AUB: No.

DR. BUTLER: Of course, one thinks of arthritis and of intervertebral disk, but without a roentgenologist, I shall pass on.

DR. AUB: I think there is a little decalcification.

DR. BUTLER: Yes, but it appears minor.

DR. AUB: I am not so sure.

DR. CASTLEMAN: The x-ray report states that there was some decalcification. The cortices were thin.

were used — if the protection purchased remained a mystery to the purchaser until he needed protection

From the public viewpoint, and considered in terms of reality certain responses to the situation in some existing plans are disturbing. When a patient who carries hospital-service insurance but has cash-indemnity medical protection inquires what a surgical fee will be, he may be asked whether he carries hospital insurance and surgical insurance, and if he replies in the affirmative the surgeon may say "That's very fortunate. It is a fine thing to have such protection. My fee will be \$200." The question about insurance may not be so abrupt or so pointed, but however it is put, the patient is aware that he has answered it. Too often a by-product of the experience, whether or not it is justified, is an unanswered question in the mind of the patient and concerning whether the fee was much larger as a result of the protection than it would have been without such protection. This question does not leave the physician in an enviable position.

Its end result, a loss of public confidence, is predictable in terms of public antagonism.

Enough has been said to indicate a primary need for practical methods in medical economics. Without far more attention to administrative methods and details and to the organization of administrative experience, no plan can proceed from broad principles to satisfactory applications. It is administrative method that will influence and finally determine the medical, social and economic soundness of any plan.

Over the country there is abundant administrative experience, but it is a misfortune that so little of it has been accumulated. Except for experience with hospitalization plans in connection with Blue Cross organizations, there has been little centralization of experience. It is for this reason that in our own work at the University of Michigan we have emphasized administration and administrative technics.

This man had been in the armed forces and at time of discharge was referred to this hospital. We tried to get the medical history from the Army. He reported that he had been sent in with a question of hyperparathyroidism because the blood chemical findings while he was in the Army had been quite abnormal. (The phosphorus values were reported to be between 2.9 and 4 mg. and the calcium as high as 14 mg. per 100 cc.) The medical officer considered a diagnosis of hyperparathyroidism and suggested to the patient on discharge that he come here for further study. Our records include some additional data. The patient had a negative urinary culture, and although we examined the urinary sediment quite carefully we could find no evidence of urinary infection. We too ruled out a renal condition as a cause for the abnormal blood chemical findings.

DR ALBRIGHT: Why did Dr. Butler think of parathyroid hypertrophy?

DR BUTLER: Because of your work, Dr. Albright.

DR ALBRIGHT: The disease is extremely rare.

DR BUTLER: You reported an excellent series of cases in the *Archives of Internal Medicine*?

DR OLIVER COPE: I might say that the patient was here during the peak of the shortage of x-ray films, which explains some of the lack of films. The X-Ray Department only had a day or two's supply of film on hand and asked us to cut down on any unnecessary examinations. We were a little confused because the original serum calcium determinations in the Army were 14 and 12 mg., and it looked as if these values were accurate. Our values were lower than anticipated. Three determinations were below 11 mg. per 100 cc., and we have accepted this as the minimum to make a diagnosis of hyperparathyroidism. That discrepancy, of course, contributed to the confusion and is emphasized because so much stress has been placed on the level of the serum calcium.

We thought that this patient had hyperparathyroidism, and I explored the right side of the neck first on a 50-50 chance. I could not find an enlarged parathyroid gland on the right side, so I went to the left and after exposing the posterolateral surface of the thyroid gland, I saw some vessels that should not have been there. They were a little large, and they went down behind the thyroid gland and the esophagus. I found what appeared to be a small adenoma in the upper gland. It was round and light in color—in parathyroid hypertrophy the glands are irregular in shape and a little more chocolate in color than an adenoma. I then found quite easily a lower parathyroid gland on the left, which appeared to be normal in size and to have the correct color.

CLINICAL DIAGNOSIS

Parathyroid adenoma

DR BUTLER'S DIAGNOSIS

Hyperparathyroidism due to either a small adenoma or idiopathic hypertrophy

ANATOMICAL DIAGNOSIS

Parathyroid adenoma

PATHOLOGICAL DISCUSSION

DR CASTLEMAN: This was a small adenoma, measuring about 8 by 6 by 4 mm. A normal gland measures 6 by 4 by 2 mm. There was a rim of normal parathyroid tissue around a part of the adenoma, which is what one should always look for in making a section of an adenoma. The presence of this rim of normal gland is evidence in favor of neoplasm and rules out hyperplasia. Hyperplasia involves the entire gland and does not leave a rim of perfectly normal tissue.

DR REIFENSTEIN: The blood chemical findings after operation are of interest. On the following day the calcium was 8.7 mg., and the phosphorus 2.6 mg. per 100 cc. Three days after operation the phosphorus was 3.8 mg. and the alkaline phosphatase 3.0 Bodansky units, and on the fourth day the calcium was 8.0 mg., the phosphorus 3.7 mg., and the phosphatase 1.9 units. The Sulkowitch test for calcium in the urine was ++++ before operation, +++ two days after operation, and + to zero thereafter.

DR CASTLEMAN: Do you think that we should consider a serum calcium of 10.7 mg. as being above normal?

DR BUTLER: The upper limit of normal, with a normal serum protein, is about 10.5 mg. This patient's serum protein, however, was down to 6 gm. per cent.

DR ALBRIGHT: Our average normal runs about 9.5 mg. per 100 cc.

DR BUTLER: The serum protein concentration of most hospitalized patients is down a little, and that means the serum calcium concentration is correspondingly lowered.

CASE 32042

PRESENTATION OF CASE

A seventeen-year-old schoolgirl entered the hospital complaining of pain in the right pubic region.

Six months before admission she first noticed a "nagging" pain in this area. It grew steadily severer and came to involve the right hip and thigh down to the knee. She walked with a limp and with increasing difficulty. She had lost about 10 pounds

DR BUTLER The trachea was slightly deviated to the left, with a question of fullness on the left. We have no x-ray films of the neck region. Parathyroid tumors are almost never palpable. The deviation was to the left and the fullness was on the left. I shall pass that over, because I cannot explain it.

At the end it states that several areas of increased density overlay the cecum. I am unable to interpret the significance of these spots, and I take it that the x-ray man could not interpret them.

We then come to a discussion of the etiology of the renal calculi, from which this man had suffered for eight years. First, we think of renal disease. It may be infection, particularly with an ammonia-producing organism. We merely have this single statement in the record that there was no evidence of renal infection. So our evidence regarding infection is extremely meager.

DR FULLER ALBRIGHT There were two negative cultures.

DR BUTLER That being the case, at the time of his last examination he did not have evidence of renal infection, but that, of course, does not rule it out.

The next thing to consider is renal stasis. The evidence again is meager, because we have no information about a renal-function test and an intravenous pyelogram. There is a type of renal disease associated with diminished ability of the kidneys to produce ammonia and thus to conserve base in the excretion of urine; this results in excessive loss of calcium and other cations (base) and thus in acidosis.

DR ALBRIGHT The serum carbon dioxide and chloride levels were normal.

DR BUTLER Serum chloride in patients with renal calculi is not infrequently found to be elevated, and because of that elevation, there is a diminished carbon dioxide, and a chloride acidosis, which accentuates the acidosis that comes from the loss of base just referred to above. This type of renal disease, with the chloride acidosis, loss of base and increased excretion of calcium, is usually a disease limited to the renal tubules, and in the tubules there is not infrequently a deposition of calcium phosphate. All the evidence so far is against that type of renal disease, largely because if there is an acidosis with any type of renal disease, and an excessive loss of calcium in the urine, the patient usually has an elevated alkaline phosphatase of the serum. Here the alkaline phosphatase of the serum was normal.

Then we come to cases of extensive renal disease, with renal insufficiency. This can be ruled out promptly with the data available, because with that type there should be an elevated nonprotein nitrogen and inorganic phosphorus, a diminished serum calcium and carbon dioxide and an elevated phosphatase, none of which were present in this case.

The second major cause of renal calculi that one

ought to think of is atrophy of bone. One might think of atrophy of disuse. In this case, however, the history is not indicative of atrophy associated with disuse. Dr Albright has recently called attention to a patient who presented a difficult differential diagnosis between hyperparathyroidism and atrophy of disuse. Dr Howard,¹ of Baltimore, has called attention to a patient who, following a fracture, was given a large amount of vitamin D and developed hypercalcemia, anuria and uremia. We have had a fairly extensive series of cases of so-called "resistant" rickets and have found that, following corrective osteotomies, there is often a marked elevation in the serum calcium and in organic phosphorus, a fall in the alkaline phosphatase to normal and complete healing of the rickets, which for years had been resistant to treatment with huge daily doses of vitamin D.

Another cause of bone atrophy may be Cushing's syndrome. There is, however, no history suggestive of a Cushing syndrome. Of course, if the demineralization of the bones as shown by x-ray were due to steatorrhea, there would not be increased calcium in the urine and calculi.

Finally, we come to hyperparathyroidism. Dr Albright and his colleagues have described a disease that can occur with minimal bone disease, but in most of the cases that they have reported there has been some elevation of the serum calcium. Because of the long-standing condition in this patient, however, and the demineralization and depletion of calcium, hyperparathyroidism may have been present without elevation of the serum calcium. Their cases showed a minimal change in the inorganic phosphorus and no elevation of the phosphatase. This patient's inorganic phosphorus was just at the lower limit of normal. The calcium of 10.7 mg for a serum protein of 6 gm is just above the upper limit of normal, by the accurate method used here.

In the absence of evidence pointing to renal infection and in the absence of such lowered carbon dioxide and of elevated phosphatase as would be consistent with a renal condition that would result in this much decalcification of bone and this degree of increased excretion of calcium, my diagnosis is either a small parathyroid adenoma or a so-called "idiopathic hypertrophy" of the parathyroid glands.

DR CASTLEMAN Hypertrophy of all four glands?

DR BUTLER The idiopathic hypertrophy that involves all four glands, the enlargement being due to an enlargement of the cells rather than to a great increase in the number of cells, such as one sees in secondary parathyroid hyperplasia following renal disease.

DR CASTLEMAN Dr Reifenshtein, would you like to comment?

DR EDWARD C REIFENSTEIN There is not much that I can add to the discussion, except to say that we never did obtain an adequate medical history.

not seen without other manifestations of the disease. In addition, this disease usually arises in the neighborhood of the joint and involves the capsule and cartilage.

Syphilis can be eliminated on the basis of the site, the character of the lesion, the age of the patient and, particularly, the absence of other evidence.

Other lesions in which the etiology is less definite must also be considered. Eosinophilic granuloma is frequently seen in young people, may occur anywhere, but generally in flat bones, and may give symptoms of pain and evidence of tumor. X-ray examination usually reveals a destructive lesion. It is seldom debilitating, however, and rarely gives rise to such symptoms as described in this patient. Osteoid osteoma usually presents as a small lesion and causes few symptoms. On x-ray examination it stands out from the surrounding osseous tissue as a delimited nidus, and there is evidence of calcified atypical new bone.

What are the possibilities of neoplastic disease? The history, symptoms and physical findings strongly suggest a neoplastic process. Osteochondroma, a benign lesion, may appear in the pubis but it can be eliminated by the x-ray evidence itself. Of the malignant lesions, there are a number of possibilities. Malignant lymphoma involving bone, particularly the reticulum-cell sarcoma type, may primarily arise in a single bone and remain confined in that location for a considerable time. It usually, however, is slowly growing and is rare in the pubis, and there are seldom constitutional symptoms, even when the tumor becomes large. Although it may exhibit evidence of bone destruction by x-ray, a soft-tissue mass is rare, except in certain locations.

Osteogenic sarcoma generally arises in the metaphyses of long bones, although one type especially, the chondrosarcoma, may arise in the pubis. Even the latter is unusual in this location. These tumors are usually prevented by the periosteum from breaking through and invading the soft tissue for a considerable period. When the soft tissues are invaded there may be evidence of calcification. In this patient there was no elevation of the alkaline phosphatase, but this does not eliminate an osteogenic tumor, particularly one of the osteolytic type. The x-ray films are not characteristic of an osteogenic sarcoma, although there is periosteal reaction, which in itself is insufficient to make a diagnosis. Pain is frequently an early symptom, but except in the late stages of the disease, disability is usually absent and the general status of the patient is surprisingly good and out of proportion to the extent of disease and the degree of malignancy.

Melanoma usually occurs in persons over forty and is generally present in multiple sites when the patient is first seen.

Metastatic lesions from primary tumors elsewhere

are unusual in this age group and seldom give rise to soft-tissue tumors.

The one tumor that fits the clinical syndrome is Ewing's sarcoma. It is a tumor of growing bone and arises from the bone marrow. The long bones are usually affected, but flat bones, particularly those of the pelvis, are not infrequently involved. The disease causes bone destruction as it develops, and by x-ray the bone has a moth-eaten look. The periosteum becomes reactive and lays down new bone, often in layers, leading to the characteristic onion-skin appearance. Sometimes radiating spicules may be seen, thus causing confusion with osteogenic sarcoma. The disease may penetrate the periosteum. This is especially true in flat bones, where the tumor breaks through the periosteum early and invades the soft tissue, such as occurred in this case. There is seldom evidence of new-bone formation in the soft-tissue mass. Pain is the most frequent initial symptom. At first it is intermittent, but as the disease proceeds it becomes increasingly severe and persistent. The tumor usually cannot be palpated until a considerable time after the onset of symptoms. It is frequently tender, firm and irregular. The overlying skin may be warm, red and edematous, which not infrequently leads to an erroneous diagnosis of osteomyelitis. Although there is no such statement in the history, the disease is often accompanied by bouts of febrile reactions, which also suggest an inflammatory process. Constitutional changes, such as weakness and loss of weight, are often seen in Ewing's sarcoma. Pain and sensory disturbances arise from growth of the tumor within the marrow cavity and eventual involvement of the sensory nerves. Depending on the location, difficulty in motion and a lump may result from soft-tissue as well as motor-nerve involvement. Laboratory evidence is of little aid in the diagnosis. Occasionally the white-cell count is abnormal, but the alkaline phosphatase is rarely elevated.

In view of the above facts the most probable diagnosis is Ewing's sarcoma.

DR SCHULZ: It might be noted that within the past two years, we have seen at least three patients with Ewing's tumor in a comparable location.

DR ERNEST M. DALAND: This patient was operated on under novocain anesthesia. A palpable lymph node overlying the ascending ramus was removed, it appeared to be merely hyperplastic. The incision was deepened down to the bone, and tumor was found. A specimen was removed with a curet. There was a gush of white fluid that at first suggested pus but then seemed more typical of the fluid often seen with Ewing's sarcoma. The wound was closed without drainage.

CLINICAL DIAGNOSIS

Ewing's sarcoma of pubis?

in weight during her illness and had become definitely weak and anorexic

The past history was negative except that one year before admission the patient had bruised her right hip in an accident. Two years before admission, she had had an attack of "arthritis" in the knees.

Physical examination revealed a somewhat undernourished, sallow girl in no acute distress. Examination of the head, neck, heart, lungs and abdomen was negative. Attached to the right pubic ramus

DIFFERENTIAL DIAGNOSIS

DR IRA T NATHANSON May we see the x ray films?

DR MILFORD D SCHULZ These films show an area of destruction involving the right pubic bone. A soft-tissue mass can be seen about it, into which spicules of bone extend. There is so-called "layering" where the periosteum has been lifted, and there seems to be a lot of disorganization of the normal medullary pattern. No remote disease is evident.

FIGURE 1 *Roentgenogram of Pelvis*

near the midline was a tender hard mass. There was tenderness also over the anterior aspect of the right femur and knee.

The temperature was 99°F, the pulse 100, and the respirations 25. The blood pressure was 120 systolic, 80 diastolic.

The hemoglobin was 12.2 gm. The white-cell count was 10,400, with 59 per cent neutrophils. The red cells and platelets appeared normal in a stained smear. The serum calcium was 9.6 mg per 100 cc, the phosphorus 2.4 mg, and the alkaline phosphatase 3.2 Bodansky units. The urine was normal.

An x-ray film of the pelvis revealed a destructive lesion involving the right superior ramus of the pubis and extending from the symphysis well toward the acetabulum (Fig 1). There was some periosteal reaction about it, and apparently a soft-tissue tumor into which radiating spicules extended. No other bony lesions were found. The lungs were clear.

An operation was performed.

DR NATHANSON An essential point to be considered in the diagnosis is whether the lesion is inflammatory or neoplastic. I shall discuss inflammatory lesions first.

Osteomyelitis is one of the most frequent of the inflammatory lesions. In favor of this diagnosis are the age of the patient, the pain and the progressive character of the process. Against it are the x-ray evidence of destruction of the periosteum, as suggested by a soft-tissue tumor, and the lack of the sequestration and new-bone formation usually seen in an osteomyelitis of relatively long duration. In osteomyelitis the periosteum is elevated but seldom penetrated. The site of the lesion is also unusual for such a disease. The white-cell count may be elevated but not necessarily so, particularly in the chronic phase of the disease. Loss of weight and generalized debility are uncommon except in the late stages.

Tuberculosis is extremely rare in the pubis, and as a rule, tuberculous lesions of this character are

FEDERAL SUPPORT FOR SCIENCE IN PEACETIME

PENICILLIN and the atomic bomb, with their enormous but opposite potentialities for good and for evil, were brought into a world at war by scientists subsidized by the federal government. These and other achievements of integrated scientific endeavor financed by federal grants have suggested the extent of the benefits that might accrue to our society in peacetime as a result of governmentally subsidized research. Over a year ago the late President Roosevelt sought an opinion on this matter from Dr. Vannevar Bush, director of the Office of Scientific Research and Development. The reply given by Dr. Bush¹ was written after consultation with committees of experts on medical science, natural science, the discovery of scientific talent and

the publication of scientific information. The report leaves no doubt in the mind of the reader concerning the immense potential advantages of a vigorous and flourishing science for improving human knowledge, economic status and health.

The need for federal support of scientific research arises primarily from the fact that the latter is expensive. Research, especially so-called "basic research," is a necessary preliminary to the applications of science, which are so obviously useful to medicine and other subjects. Basic research is carried out for the most part in universities or in nonprofit research institutes. It is often time consuming, always obscure and, because it seldom leads directly to practical results, seems to yield little tangible value relative to its cost. Applied research also is often expensive, but with practical objectives already clearly in view it is likelier to receive support from industry or other private sources than is basic science. Unfortunately, there is ample evidence that research is receiving progressively less support in the form of income from endowment, grants from foundations and private donations. Indeed, many of the seventy-seven medical schools in this country have never had sufficient funds to carry on more than a small amount of investigation. There is also a chronic deficiency of trained scientific talent, and this scarcity has been acutely increased by diversion to the battle fronts of students who otherwise would be preparing for careers in science. To restore university research even to its prewar level of scientific personnel will be a costly and prolonged educational undertaking. To accelerate scientific progress by discovering and fully utilizing the scientific talent and by developing the necessary laboratories of the country as a whole exceeds the capacity of the private sources of income that can be visualized today.

As physicians, we are impressed in our daily lives with the difficulties of appropriately applying the established findings of medical science to the individual patient. Yet, it is only necessary to consider the increasing incidence of cancer and degenerative diseases and of mental illness to understand that more hospitals and better diagnostic procedures, however useful, do not provide a solution. Better educational facilities for doctors also

DR NATHANSON'S DIAGNOSIS

Ewing's sarcoma of pubis

ANATOMICAL DIAGNOSIS

Ewing's sarcoma of pubis.

PATHOLOGICAL DISCUSSION

DR BENJAMIN CASTLEMAN The biopsy confirmed Dr Nathanson's diagnosis of Ewing's sarcoma. The lymph node showed only hyperplasia.

DR DALAND The patient was treated with the million-volt machine, receiving a total of 5400r, half anteriorly and half posteriorly, over a period of approximately three weeks. After the second treatment she had practically complete relief. After the fourth treatment she was able to move her leg quite normally and opiates were stopped. By the time the treatments were completed, she had complete relief of pain and normal hip motion.

d would tend to promote the special interests of these governmental departments. They contend that, although knowledge of and liaison with governmental scientific activities should be maintained, the board should not be burdened with "efficiently programming and co-ordinating all federally financed research and development," as recommended by the Kilgore Bill. On the subject of the management of patients arising in the course of research supported in whole or in part by the foundation, the Magnuson Bill is silent. The members of the Committee Supporting the Bush Report regard this omission as desirable, because they believe that to specify a partial solution of this complex problem, as is attempted in the Kilgore Bill, is premature in view of the fact that a study of the Government's patent policy is now in progress by a committee headed by the Secretary of Commerce.

In his message to Congress President Truman recommended the inclusion of the social sciences within the framework of the proposed foundation. Both bills as presented to the Senate committees in amended form include the social sciences — sociology, political science, economics, law and so forth — as fields in which scientific research and development are to be supported. Although recognizing the national importance of social studies, the Committee Supporting the Bush Report expresses the view that a board fully competent to administer grants for research and fellowships in the basic sciences would not be qualified for corresponding duties with respect to the social sciences. Consequently, it is suggested that the subject of research and education in the social sciences should be taken care of in a separate body, set up, presumably, after a factual study of the needs for federal support of the social sciences comparable to that which led to the framing of the Bush report.

On December 21, a third bill, sponsored by Senators Kilgore, Johnson, Pepper, Fulbright and Saltonstall was introduced. This bill retains the general objectives with respect to research and education of its predecessors, and meets some of the objections to the Kilgore Bill that have been raised by the Committee Supporting the Bush Report. Thus, *ex-officio* representation of governmental

departments is not required on the advisory board, but is provided for in a separate interdepartmental committee. The administrator, who is appointed by the President remains in charge of the foundation. He is required to consult and advise with a board composed of nine persons appointed by the President but also including the chairmen of from eight to eleven divisional scientific committees appointed by himself with the approval of the board. Patents taken out in the course of research and development authorized by contracts between the foundation or any other governmental agency and a private organization are, with certain exceptions, based on the extent of the latter's contribution, to be freely dedicated to the public. A division of social sciences is retained. Expenditure of 25 per cent of the funds is placed beyond the judgment and discretion of the administrator and his committees. It is provided that this sum be distributed among the tax-supported colleges and universities, including the land-grant colleges, according to a formula based partly on state populations. The germ of this proposal appears nowhere in the Bush report.

Subsequently, another group of scientists, comprising the Committee for a National Science Foundation, released a statement outlining its views concerning the feasibility and practicability of scientific advance under governmental auspices. The six major points are as follows: the necessity for federal support of research to supplement private funds, the inclusion of provision for all fields of fundamental scientific inquiry relative to national interest, the publication of findings resulting from federally financed research and dedication of these findings to "the welfare of the people", the training of research personnel, and the devising of a plan of organization that meets the major objections to vesting administrative responsibility in either a governing board or a single administrator.

Obviously there can be honest differences of opinion concerning the best legislative approach to the vital problem of federal support for the scientific endeavor of the Nation. In accordance with democratic procedure, the evidence for these different points of view has been presented at the Senate hearings, and it is to be hoped that Congress

will not suffice, for nowhere in the world today exists the knowledge of how to prevent or cure many of the important causes of death or chronic disability. If medicine is to continue to advance, science has to find the answers

Granted then that the need for research is so great that federal support is required, the question of fundamental importance to scientists and the public is whether such powerful assistance can be given without impairing the independence, imagination and freedom in experimental endeavor of the individual investigator, which is so essential for scientific progress. The Bush report considers that this is possible, provided that certain basic principles remain inviolate. Thus, there must be stability of funds for long-range programs administered by an agency headed by competent and impartial citizens. The agency should promote research in organizations outside the federal government, and to these should be left, so far as possible, the choice of subject and method of investigation.

Last July the essential purposes and plan of the organization outlined by the Bush report were embodied in a bill that was introduced by Senator Magnuson, of Washington. This bill proposed the establishment of the National Research Foundation, with divisions concerned with support of research in various departments of science, including medicine, scholarships for promising science students throughout the nation and the promotion of international exchange of scientific information. A few days later a bill was introduced by Senator Kilgore, of West Virginia, proposing the establishment of the National Science Foundation, also committed to the desirable objectives just mentioned.

The differences in the organizational features of the two bills indicate why the Magnuson Bill re-

ceived the enthusiastic support of most of the scientists who testified at the hearings on both bills, which were held during October before joint Senate committees. Certain government officials, however, have expressed disapproval of the plan favored by the scientists. Alarmed by the potential dangers to the future of scientific research that they foresaw might result from significant modifi-

cations of the original Magnuson Bill, a group of scientists and educators comprising the Committee Supporting the Bush Report² recently addressed an open letter to President Truman. In this communication the principles on which they believe that sound legislation should be based are stated and certain features of the Kilgore Bill are adversely criticized.

In the first place, the men comprising this group emphasize that the Magnuson Bill is designed to implement the plan developed by the careful studies of Dr. Bush and his advisory committees. They are in favor of the provision of the Magnuson Bill that places the direction of the foundation in the hands of a board composed of laymen and scientists appointed by the President, with a full-time administrator appointed by and responsible to the board. They express opposition to the provisions of the Kilgore Bill for the appointment by the President of a single director, together with an advisory board, because they believe that the director "should be the agent — not the master — of the board." They point to what they regard as a further defect of the Kilgore plan, namely, the provision that calls for representation on the advisory board by *ex-officio* members responsible for the scientific programs of the Army, Navy and other governmental departments. This representation, they allege, would not make for a strong and impartial advisory board.

MASSACHUSETTS MEDICAL SOCIETY POSTWAR LOAN FUND

The Postwar Loan Fund has been set up, and all discharged medical officers who were members of the Massachusetts Medical Society in good standing at the time of their entry into the service may apply for loans from this fund. For further information apply to

†Four year average

COMMENT

Measles was reported less frequently during 1945 than during any year since 1907. During the month of December, however, there were three times as many cases as in December, 1944.

Scarlet fever was 50 per cent lower in December than it was during the corresponding month in 1944. In fact, from the months of August through December, 1945, the disease was reported less frequently than during a comparable period of months since 1940.

Cases of pneumonia were fewer than last year, in fact the number during December was lower than that for any December since reporting of pneumonia began in 1918.

GEOGRAPHICAL DISTRIBUTION OF CERTAIN DISEASES

Anterior poliomyelitis was reported from Billerica, 1, Boston, 2, Concord, 1, Lowell, 1, Manchester, 1, Pittsfield, 1, Somerset, 1, Winthrop, 1, Worcester, 2, total, 11.

Anthrax was reported from Franklin, 1, total, 1.

Diphtheria was reported from Belmont, 1, Boston, 8, Franklin, 1, Hingham, 1, Lowell, 1, Millville, 1, Monterey, 1, Peabody, 1, Sndbury, 1, Taunton, 2, Tyngsboro, 1, Weyland, 1, total, 20.

Dysentery, amebic, was reported from Camp Edwards, 1, Fort Devens, 1, Waltham Regional Hospital, 2, total, 4.

Dysentery, bacillary, was reported from Boston, 2, Braintree, 2, Cambridge, 1, Chelsea, 1, Lowell, 1, Waltham, 2, Wrentham, 3, total, 12.

Malaria was reported from Amherst, 1, Arlington, 1, Belmont, 1, Boston, 9, Brookline, 1, Cambridge, 1, Camp Edwards, 6, Chicopee, 1, Fort Devens, 31, Gloucester, 1, Hopedale, 1, Hull, 1, Lynn, 1, Medford, 1, Needham, 1, New Bedford, 1, Pittsfield, 1, Quincy, 1, Somerville, 2, Springfield, 1, Sutton, 1, Uxbridge, 1, Waltham, 1, Waltham Regional Hospital, 9, Wellesley, 1, Winthrop, 1, Worcester, 5, total, 83.

Meningitis, meningococcal, was reported from Adams, 1, Arlington, 1, Boston, 3, Great Barrington, 1, Lowell, 2, Nahant, 1, Somerville, 1, Springfield, 1, Waltham Regional Hospital, 1, Watertown, 1, total, 13.

Meningitis, Pfeiffer bacillus, was reported from Arlington, 1, Methuen, 1, total, 2.

Meningitis, pneumococcal, was reported from Worcester, 1, total, 1.

Meningitis, staphylococcal, was reported from Wrentham (State School), 1, total, 1.

Meningitis, other forms, was reported from Boston, 3, total, 3.

Meningitis, undetermined, was reported from Cambridge, 1, Haverhill, 1, total, 2.

Salmonella infections were reported from Cambridge, 1, Haverhill, 1, Malden, 1, North Andover, 1, Sheffield, 1, total, 5.

Septic sore throat was reported from Attleboro, 4, Boston, 3, Cambridge, 2, Fall River, 1, Medford, 1, Merrimac, 1, Williamstown, 1, total, 13.

Trichinosis was reported from Falmouth, 1, total, 1.

Typhoid fever was reported from Boston, 1, Methuen, 1, total, 2.

Undulant fever was reported from Adams, 1, Ashfield, 1, Brookline, 1, Fort Devens, 1, Hatfield, 1, North Andover, 2, Northampton, 1, Palmer, 1, Taunton, 1, total, 10.

CONSULTATION CLINICS FOR CRIPPLED CHILDREN IN MASSACHUSETTS UNDER THE PROVISIONS OF THE SOCIAL SECURITY ACT

CLINIC	DATE	CLINIC CONSULTANT

Physicians referring new patients to clinics should get in touch with the District Health Officer to make appointments.

MISCELLANY

CHANGES AT HARVARD SCHOOL OF PUBLIC HEALTH

Plans to increase the scope and importance of the Harvard School of Public Health were recently announced by President Conant. One of the world's foremost medical scientists, Brigadier General James Stevens Simmons, chief of the Preventive Medicine Service, Office of the Surgeon General, United States Army, has been appointed dean, succeeding Dr. Edward G. Huber, who has served as acting dean for the past several years. The Rockefeller Foundation has granted \$1,000,000 for expenses of the school from July 1, 1946, to June 30, 1956, and Harvard University has set aside a sum of \$750,000 to supplement the present endowment fund of the school.

In a reorganization intended to make this one of the outstanding research and teaching institutions in the world, the School of Public Health will have co-equal status with the Harvard Medical School and other professional divisions of the University. In addition to its present building at 55 Shattuck Street, Boston, the school will occupy the former Collis P. Huntington Memorial Hospital. Acquisition of this nearby hospital, which is to be remodeled, will give the school an additional 40,000 square feet of floor space.

SECTIONAL MEETINGS OF AMERICAN COLLEGE OF SURGEONS

The American College of Surgeons announces the resumption in 1946 of its sectional meetings, which during the war were replaced by one-day war sessions. Ten two-day meetings are planned, to begin in Minneapolis, with headquarters at the Radisson Hotel, on January 28 and 29. The second meeting will be held in the Hotel Jefferson, St. Louis, on January 31 and February 1, the third at the Tntwiler Hotel, Birmingham, on February 8 and 9, the fourth in the William Penn Hotel, Pittsburgh, on March 11 and 12, the fifth at The Copley-Plaza, Boston, on March 18 and 19, the sixth in the

will produce a satisfactory measure. Scientists do not pretend to set themselves up as authorities on administrative procedure, but their own experience justifies their right to profess knowledge of the type of organization in which they would have confidence and of the particular conditions necessary to the most fruitful efforts of the research worker. Thus, what is wanted most of all in a national research foundation is not so much co-ordination by an efficient central organization but a means for impartially discerning and aiding the all important, but remote and often obscure, peripheral human units of the plan — those men and women whose curiosity about the phenomena of nature is truly compelling. The scientists are right when they say that in such persons lie the most important scientific resources of the Nation in peace, as has been so clearly shown to be the case in war.

DEATH

KNOWLTON — Edward A. Knowlton, M.D., of Holyoke, died August 22. He was in his sixty-third year.

Dr. Knowlton received his degree from Tufts College Medical School in 1909. He was senior visiting surgeon, Holyoke Hospital, visiting surgeon, Providence Hospital, and consulting surgeon to the Belchertown State School. He was former chairman of the Massachusetts Board of Registration in Medicine. He was a fellow of the American Medical Association and the American College of Surgeons.

MEDICOLEGAL ABSTRACT

Relation of Patient and Physician. Liability for malpractice. Where a plaintiff is injured by an instrumentality entirely within the defendant's control under circumstances that would not arise unless someone had been negligent the courts apply the doctrine of *res ipsa loquitur*. The plaintiff by showing such circumstances raises a sufficient inference of negligence to go to the jury and, unless the defendant comes forward with a satisfactory explanation, to obtain a verdict. Various courts have made different applications of this doctrine — some strict, some liberal.

In a recent Arkansas case the plaintiff had a needle imbedded in her foot. The defendant examined her with a fluoroscope and performed an exploratory operation. About four or five days later the plaintiff's foot became inflamed.

The plaintiff sought to found her case on *res ipsa loquitur*. The court said that the fact that un-

favorable results do not ordinarily follow such a treatment does not raise an inference of malpractice by itself when unfavorable results do happen to occur. It went on to say that *res ipsa loquitur* does not apply to the practice of medicine and surgery or to the use of x-ray machines. Medicine and surgery are inexact sciences, and doctors are not guarantors of results. The implication of this last sentence is that *res ipsa loquitur* would only be applied where an injury raised an absolutely necessary inference that someone had been negligent. — (*Renton v. McGehee*, 186 S.W. [2d] 779, April 16, 1945, Arkansas.)

A somewhat different view of the doctrine was taken in a recent California case. The plaintiff was given a general anesthetic, and one of the defendants performed an appendectomy. When the plaintiff awoke he had a sharp pain in the right shoulder. After leaving the hospital this condition grew worse, he was unable to rotate his arm, and the arm became paralyzed and atrophied.

He brought suit against the doctor who had diagnosed his condition as appendicitis (the case is not clear whether this doctor was present at the operation), the doctor who performed the operation, the doctor who owned and operated the hospital, the anesthetist in the employ of the hospital and the special nurse who was in attendance after the operation.

The plaintiff introduced expert testimony to the effect that the paralysis was of traumatic origin. He then sought to invoke the doctrine of *res ipsa loquitur* to infer the defendants' negligence.

The trial court in entering a nonsuit as to all defendants found that there was no showing which defendant had control of the instrumentality causing the injury and that, since all defendants were not responsible for the acts of each other, the doctrine could not be applied. The plaintiff appealed and the judgment was reversed.

The court said that the unconscious patient is entitled to an explanation at least as much as the conscious pedestrian who is struck by an object coming from a building or other structure under the defendant's control. Concerning the relation of the various defendants, all of whom could hardly be held for a single act of negligence, the court found that all were temporary servants of the doctor performing the operation (*quere*) and that in any event the trial might absolve some of them from liability. Despite these difficulties the rule must be applied liberally so that those who were in a position to explain the injury are compelled to do so. Someone must in fact have been negligent and ought to be liable. The fact that the patient was unconscious and cannot identify the liable party does not deprive him of his rights. All the defendants were present for a common purpose.

The view taken here is that the doctrine applies because the defendants ought to have the burden

A TICK-BORNE EPIDEMIC OF TULAREMIA

LIEUTENANT COLONEL WILLARD B. WARRING, M.C., A.U.S., AND
MAJOR J. STERLING RUFFIN, JR., M.C., A.U.S.

BECAUSE tularemia has been generally regarded as a relatively infrequent disease, and because emphasis has been placed on its transmission by contact with animals, especially rabbits, an epidemic of 50 cases most of which were caused by tick bites is reported. These cases occurred among soldiers in the Tennessee maneuver area from March to December, 1943. Grouped according to the Hughes¹ classification of tularemia, these cases were divided as follows: ulceroglandular type, 35 cases; pulmonic type, 11 cases; glandular type, 3 cases; mixed ulceroglandular and pulmonic type, 1 case. All patients but 1 recovered.

Tularemia has been reported in every state of the Union except Vermont.² *Pasteurella tularensis* has been found in over twenty kinds of wild life.³ Ticks, deer flies and cottontail rabbits are the three greatest sources of infection for man.⁴ Transference of the disease between human beings has been reported.⁵

Although transmission of *P. tularensis* by several varieties of ticks has been demonstrated,^{3, 6, 7} a survey of the area in which the present cases arose

were bivouacked in an area highly infested with ticks, and since *P. tularensis* can penetrate the unbroken skin,¹² it seems justifiable to assume that the ticks were the transmitting agents.

The onset of symptoms in the proved cases of tick bite occurred within one to twenty-one days. In 50 per cent of all cases the onset was acute. The outstanding symptoms were generalized aching, especially marked in the lumbosacral region and the lower extremities, headache, shaking chills, debilitating sweats, pain and tenderness in the regional lymph nodes, unproductive cough, weakness, dizziness, nausea, vomiting, anorexia and abdominal pain. In 5 cases, abdominal pain and tenderness, together with spasm of the abdominal muscles,

Total	50	

revealed that all specimens were *Amblyomma americanum*, the so-called "lone-star tick."^{8, 9} Parker¹⁰ was unable to demonstrate *P. tularensis* from these ticks by culture, but previous studies in his laboratory had shown that the nymphs and larvae of *A. americanum* of the same generation transmitted *P. tularensis*.¹¹

A definite history of tick bite prior to onset of illness was obtained in 32 of the 50 cases in this series (Table 1). Five appeared to be due to direct contact with rabbits. In 13 cases, a history of tick bite could not be obtained. Since these soldiers

suggested some acute disorder within the abdomen. Severe prostration was the rule. In 6 severely ill patients, marked delirium followed by drowsiness was present, the former being most marked in the pulmonic type of disease, which was also characterized by chest pain, unproductive cough and dyspnea out of proportion to the physical findings.

At the site of infection or bite were punched-out ulcers varying from 0.5 to 3 cm in diameter. The edges were raised, irregular and surrounded by induration and erythema. The primary ulcers were found on the upper and lower extremities, perineum, buttocks, lower abdomen and scapular region (Table 2). In the majority of cases there was only one ulcer.

Mount Royal Hotel, Montreal, on March 22 and 23, the seventh at the Statler Hotel, Detroit, on March 26 and 27, the eighth in the Utah Hotel, Salt Lake City, on April 8 and 9, the ninth at the Multnomah Hotel, Portland, Oregon, on April 12 and 13, and the last in the Biltmore Hotel, Los Angeles, on April 17 and 18.

The medical profession at large, medical students and hospital executives are invited to join with the fellows of the College in these meetings. The invitation has been extended to the entire medical and hospital profession because only local meetings of medical groups have been held during the past three or four years and the College recognizes the need for disseminating information about new methods and therapies through larger meetings addressed by nationally prominent speakers.

CORRESPONDENCE

A CORRECTION

To the Editor In the July 12, 1945, issue of your journal, an item was published relating to a court case in Vermont where a decision was rendered involving a man by the name of Haskins, where suit had been brought for compensation for Christian Science treatment.

I believe it is only just to you and your readers to know that Haskins was never listed as a Christian Science practitioner in *The Christian Science Journal*, which is the organ of the Christian Science church containing a list of those who have the necessary qualifications to be recognized as authorized practitioners by The Christian Science Board of Directors. Although he was at one time a member of the Christian Science church, he is no longer a member.

It is true, as stated in your report, that "it is a violation of the rules of the church for a Christian Science practitioner to bring suit at law to recover for treatments given to a patient."

MEDICAL CONFERENCE PROGRAM

Friday, February 1 Diseases of the Orbit. Dr. Benjamin Sachs

Wednesday, February 6—Obstetric Trends during the Last Five Years. Dr. Alonzo K. Paine

Friday, February 8—Physiologic Evaluation of Quarter-master Clothing and Equipment. Colonel John H. Talbot

Wednesday, February 13—The Treatment of Laennec Cirrhosis. Dr. Roy C. Crosby

Friday, February 15—Diagnosis of Congenital Heart Disease by Venous Catheterization. Dr. Lewis Dexter

Wednesday, February 20—Psychologic Aspects of the Menstrual Cycle. Dr. Norris T. Flanagan

Friday, February 22—Holiday

Wednesday, February 27—Practical Aspects of Ringworm Diseases. Dr. Ernst Bernhardt.

On Tuesday and Thursday mornings, Dr. S. J. Thannhauser will give medical clinics on hospital cases. On Saturday mornings, clinics will be given by Dr. William Dameshek.

All morning conferences are open to the medical profession.

NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, February 7, in the classroom of the Nurses' Residence at 7:15 p m. Dr. Siegfried Thannhauser will discuss an interesting case of jaundice. Dr. Helena M. Murphy will be chairman.

UROLOGY AWARD

The American Urological Association offers an annual award, not to exceed \$500, for an essay (or essays) on the result of some specific clinical or laboratory research in urology. The amount of the prize is based on the merits of the work presented, and if the Committee on Scientific Research deems none of the offerings worthy, no award will be made. Competitors shall be limited to residents in urology in recognized hospitals and to urologists who have been in such specific practice for not more than five years. All interested should write the secretary for full particulars. The selected essay (or essays) will appear on the program of the meeting of the American Urological Association to be held at the Netherland Plaza, Cincinnati, July 22 to 25. All essays must be in the hands of the secretary, Dr. Thomas D. Moore, 899 Madison Avenue, Memphis, Tennessee, on or before July 1.

previous day he had removed from his right thigh a tick that had been present for an unknown period of time

Physical examination revealed an acutely ill man with a small punched-out ulcer on the anterior aspect of the right upper thigh and enlarged, smooth, discrete lymph nodes measuring between 2 and 4 cm in diameter in the right inguinal region

Fever varying between 101.8 and 104°F continued for 12 days, after which remissions occurred for 6 days, with a gradual decline by lysis to normal levels. The white-cell count varied from 6250 to 11,400. Repeated dark-field examination of material from the ulcer, the Frei test, the Kahn test and urinalyses were all negative. Culture from the ulcer showed a nonhemolytic *Staphylococcus albus*. The serum agglutination titer for tularemia on the 20th day was 1:10,240.

Convalescence was uneventful. At the end of 30 days the ulcer had healed and the inguinal nodes were nontender, although still enlarged. The patient was discharged to duty complaining of slight weakness.

CASE 2 A 30-year-old soldier was admitted to an evacuation hospital on May 28, 1943, complaining of generalized

On July 29, the patient was transferred to another station hospital and thence to a general hospital and finally to another general hospital. During this interim the ulcer had healed, but the right axillary nodes had become more enlarged and had gradually softened. A thick, greenish exudate was removed from these nodes by aspiration on several occasions.

At the latter general hospital, 3300 units of penicillin was injected into one of the abscess cavities after aspiration, but this appeared to make the abscess worse. By October 11 the abscess had healed. The agglutination titer on August 27 was 1:1282. Because of weakness, the patient remained in bed until October 27. Later he was placed in a group participating in a reconditioning program. The total hospitalization period was 203 days.

Mixed Ulceroglandular and Pulmonic Type

CASE 3 A 24-year-old soldier was admitted on June 18, 1943, complaining of generalized aching, headache, malaise, fever, sweating, colicky abdominal pain, and diarrhea of 2 days' duration. He had removed ticks from his body on several occasions during the previous 2 weeks.

Physical examination revealed an acutely ill, oriented

FIGURE 1 Case 3

The interpretations of these bedside x-ray films were as follows: A (7-19-43) "There is hilar adenopathy on the left. The lung fields are too dark to reveal any interstitial changes"; B (7-21-43) "There is a considerable amount of peribronchial infiltration in the right base. There is a small area of consolidation in the region of the third interspace on the left. The mediastinum appears to be widened and irregular"; C (7-24-43) "There is a massive pleural effusion involving the left chest, but lung markings are seen in the upper third. The hilar adenopathy appears to be practically the same as that in the previous films. The infiltration in the right base has slightly cleared. The mediastinum is widened."

aching, headache, fever, chills, sweats, backache and slight stiffness of the neck. Two days previously a tick had been removed from the right arm. Physical examination was negative except for a temperature of 100°F.

On June 7, the patient was transferred to a station hospital because of fever of undetermined origin. He was acutely ill, and his previous symptoms had become exaggerated. Moreover, the patient presented signs of cerebral irritation, which was manifested by restlessness, irritability and mental confusion. The temperature on this admission was 105.4°F. Physical examination showed a small punched-out ulcer on the right forearm just distal to the elbow, enlarged, tender lymph nodes in the right axillary region, slight nuchal rigidity and abdominal distention. The white-cell count was 13,000. The results of spinal-fluid examination were within normal limits. An agglutination test for tularemia on blood taken at the time of admission was negative. On June 8, a discrete, red, macular rash appeared on the trunk and arms. The abdominal distention became more marked, and the patient vomited moderate amounts of a coffee-colored material and became stuporous. For 8 days there was continuous fever ranging between 103 and 105°F, but on the 14th day the temperature began to drop by lysis and symptoms gradually subsided. On June 15, the agglutination titer for tularemia was 1:1280.

patient with a temperature of 103.6°F and marked tenderness over the right costovertebral angle. The white-cell count was 10,700. The urine gave a +++ test for albumin.

On July 21, an unproductive cough and pain on inspiration developed in the lower right chest. The patient appeared critically ill and was cyanotic and dyspneic. Physical examination and x-ray examination of the chest revealed signs of consolidation in the right lower lobe and a widened mediastinum (Fig 1B). The pneumonic process rapidly progressed until it involved almost all the left lung and the middle and lower lobes of the right lung. A pleural effusion developed in the left side of the chest (Fig 1C). The spleen was palpated 2 fingerbreadths below the left costal margin. The temperature varied between 101.2 and 105.4°F. The patient became delirious, and the prostration, dyspnea, and cyanosis increased. Blood, stool and urine cultures were negative. Repeated sputum examinations were negative for acid-fast bacilli. On the 6th day of the disease, the white-cell count was 6750 and remained at this level until the death, which occurred on the 10th day.

Autopsy The significant post-mortem findings were as follows: The left chest contained 1000 cc. of cloudy, straw-colored fluid, in which were flecks of yellow fibrinous material. Findings consistent with pneumonia were present in the entire left lung and the lower lobe of the right lung. In addition, in the left upper lobe there were many indurated areas, which

Enlarged regional lymph nodes, single or multiple, and varying from 2.5 to 6 cm in diameter were found in every case with an obvious primary lesion and in 3 without one. The nodes were at first nontender, but as they increased in size they became tender and fluctuant and the overlying skin became reddish purple and thin. If not incised, these nodes usually suppurated and drained. In 38 cases with nodular involvement, the nodes were suppurative in 35 and nonsuppurative in 3. In 6 cases, nodes in other areas enlarged simultaneously with regional nodes draining the affected area, they slowly resolved without softening.

In 8 cases, a diffuse, erythematous, maculopapular eruption, distributed over the entire body but most pronounced over the extremities, appeared between the fifth and eleventh days of the disease. In 2 cases, it was morbilliform. The average duration of the eruption was eight days.

Two cases with acute fibrinous pleurisy and 3 with pleural effusion were encountered in the ulceroglandular type. In the pulmonic type, findings consistent with pneumonia were present. In the more serious of these cases, there appeared definite areas of consolidation involving one or several lobes, accompanied by cyanosis and dyspnea. Resolution of the pneumonia began in the third week and was extremely slow, requiring from five weeks to six months for completion.

Between the second and the fourth week, pleural effusion occurred in 9 of the 11 patients with pure pulmonic involvement. After repeated thoracenteses, the effusion subsided in ten days to five months, with an average of seventy-five days. The fluid was either greenish or serosanguineous, its specific gravity varied from 1.015 to 1.022 and the predominating cells were lymphocytes. Direct smears showed no organisms.

In 1 case, severe dyspnea was caused by a mass in the mediastinum, which gradually increased in size. The patient died on the tenth day of illness, and at autopsy the mediastinum was filled with enlarged lymph nodes.

In early stages of the disease, fever was continuous, varying between 101 and 105°F. Later there were morning remissions, and in the majority of cases the fever fell by lysis to normal in the fourth week of the disease. In patients with pleural effusion, thoracentesis caused a drop in temperature and a decrease in respiratory embarrassment.

The primary skin lesion healed with scar formation in four to seven weeks.

The patient's reaction varied from mild constitutional symptoms to marked prostration, depending on the severity of the disease. Convalescence was slow. Weakness, lassitude and loss of weight persisted for an indefinite period of time. Most of the patients have been in the hospital for three to six months and are still convalescing.

There was nothing significant in the white-cell

counts, since they varied from normal to 15,150. The differential count revealed a slight shift to the left.

In all 50 cases, diagnosis was confirmed by agglutination tests which were positive in dilutions of serum varying from 1:320 to 1:10,240. The agglutinins were usually present in the second or third week of the disease, and the highest titers were reached between the third and the eighth week—a fact that is of diagnostic significance. Cross agglutination occurred in 5 cases with *Brucella abortus* and in 1 case with *Proteus* OX 19. All were excluded by the laboratory procedure in which a tularemic serum agglutinates a suspension of *P. tularensis* more rapidly and to a higher titer than it does *Br. abortus*, *Br. melitensis* or *Proteus* OX 19 antigens.²

Cultures made from the pleural exudate on the usual laboratory mediums to exclude the presence of pathogenic bacteria were negative. Smears of material from the ulcers, suppurating nodes and sputum revealed no *P. tularensis*. Guinea pigs were inoculated but unfortunately died of some other infection that became epidemic in the animal house.

The treatment was nonspecific and supportive. Oxygen given early to patients with pneumonia and continued throughout the acute stage seemed to offer the best chance for recovery. Wet dressings and bland ointments were applied to ulcerated lesions. When softening of regional nodes occurred, surgical incision and drainage were instituted. Thoracentesis performed in cases with pleural effusion caused an amelioration of symptoms. Administration of sulfathiazole and sulfadiazine was without apparent benefit.

Diseases with which tularemia may be readily confused include sporotrichosis, actinomycosis, meningitis, typhoid fever, Rocky Mountain spotted fever, acute infectious mononucleosis, lymphogranuloma inguinale, typhus fever, pneumonia, measles, tuberculosis, malaria and undulant fever.

The laboratory methods of confirming the diagnosis are three in number—growth of the organism from the blood or pleural or spinal fluid on a blood cysteine agar medium, inoculation of guinea pigs with this material and repeated serum agglutination tests.⁶ The agglutination test is regarded as one of the most reliable confirmatory tests in the field of serology.³ Ransmeier and Ewing¹³ have shown that a positive tularemic agglutination titer may persist for a number of years. We have had no experience with Foshay's¹⁴ intradermal test.

The following cases are representative of the various types of tularemia that were encountered.

CASE REPORTS

CASE 1. A 22-year-old officer was admitted to the hospital complaining of generalized aching, chills and fever. The

PENICILLIN IN THE TREATMENT OF BRONCHIECTASIS*

A Preliminary Report

I D BOBROWITZ, M D,† JAMES S EDLIN M D,‡ SYDNEY BASSIN, M D,§ AND

J STANLEY WOOLLEY, M D ¶

OTISVILLE, NEW YORK

REPORTS on the use of penicillin in the treatment of pleural and pulmonary suppurative conditions are appearing in increasing numbers. A favorable response has been achieved in acute pneumonitis¹⁻⁴ and pulmonary abscess.^{2, 3} The best effects have been obtained in infections caused by streptococci, staphylococci, pneumococci and actinomyces, and the poorest in those with mixed anaerobic bacteria. These cases were treated by intravenous or intramuscular administration of the drug. Penicillin has also been utilized satisfactorily in hemothorax to prevent infection.^{2, 5} Acute pyogenic empyemas have been cleared of organisms and the toxemia prevented or reduced;⁴⁻⁶ by aspiration of chest fluid and the intrapleural instillation of penicillin. Mixed-infection empyemas have been similarly treated;⁵ to prepare patients for thoracoplasty.

White et al.⁷ used penicillin in the prevention of postoperative empyema following lung resection. Forty-one patients had pneumonectomy or lobectomy for bronchiectasis, lung abscess, tuberculosis or neoplasm. Twenty-one of them received 150,000 units of penicillin daily — 12,500 units intramuscularly every two hours — for one week preoperatively and for two weeks postoperatively; and 20 patients served as controls. None of the penicillin-treated patients developed empyema, whereas 12 or 60 per cent of the controls did so. Penicillin was given to 12 patients with lung resection for bronchiectasis and multiple lung abscesses. Five of them had a reduction in sputum volume before operation, and 2 had a thinning and decrease in purulence of sputum. In 6 cases, penicillin given in experimental cases for seven days before operation caused hemolytic streptococci to disappear from the sputum soon after therapy was instituted. Pneumococci and streptococci were usually unaffected, although in an occasional case these organisms disappeared. Gram-negative bacilli frequently occurred and often persisted throughout the period of hospitalization. The bronchial secretions of 2 patients were tested for the presence of penicillin, and none was detectable in either. Blood samples revealed varying concentrations of penicillin. These authors believe that the preoperative administration of penicillin serves to control acute and chronic infection in the pul-

monary tissues. This reduces the possibilities of postoperative infections and affords a maximum drug effect at the time the pleural space is exposed to bronchial contamination.

* * *

The present study was made to determine the value of penicillin in the treatment of bronchiectasis. Various modes of administration were utilized — intramuscular, intratracheal or intrabronchial and inhalation (nebulization) and combinations of these methods. It was particularly planned to estimate the advantages of the topical or bronchial effect of the drug.

The treatment was given to 12 patients — 10 men and 2 women — 2 of whom were Negroes. The ages varied from sixteen to thirty years. Therapy was initiated in the first case on August 9, 1944 and in the last one on April 18, 1945. The first nine patients were treated at the Municipal Sanatorium, Otisville, New York, and the last three at St. Clare's Hospital, New York City. All patients followed up were seen at the St. Clare Clinic.

PLAN OF STUDY

For a few days to a week or more prior to penicillin administration and throughout the hospitalization period, the patients were kept on postural drainage — two or three times a day for ten to fifteen minutes. When the penicillin was administered intratracheally, postural drainage immediately preceded the treatment to improve the topical action of the drug. This procedure also facilitated the collection of the sputum and assured a satisfactory total daily output. The patients were instructed to continue postural drainage after discharge.

The sputum was examined frequently and often daily before, during and after treatment, the twenty-four-hour amount being carefully determined either by measure or by weight, and the presence or absence of odor was noted. A gram-stained smear was made of each specimen received, — in twenty-four-hour collections, — and the presence and relative number and kinds of organisms were noted. A Fontana-stained smear was examined for each of the Otisville patients. Sputum cultures were done from time to time.

The sputum in established bronchiectasis usually exhibits a highly diversified flora that includes gram-positive and gram-negative organisms. Since the

§Associate visiting physician, Municipal Sanatorium.

¶Director of laboratory, Municipal Sanatorium.

were nodular in form and consisted of necrosis and caseation. The nodules varied from 1.5 to 3.0 cm in diameter. The mediastinum contained large masses of purple-black, firm, enlarged lymph nodes, varying from 1.5 to 4.0 cm in diameter. They were anterior to the esophagus and extended to the hilar region of each lung. All showed areas of necrosis and caseation. All the viscera, including the brain, showed moderate congestion. Both the spleen and the liver were markedly enlarged. The spleen showed necrosis and cell fragmentation, and the liver contained areas of abscess formation. Blood taken from the heart revealed a positive tularemia agglutination titer of 1:320.

Pulmonic Type

CASE 4 A 23-year-old officer was admitted on October 9, 1943, complaining of generalized aching, chills, fever and unproductive cough. During the previous 10 days he had been bitten by many unidentified insects. Since he had been billeted in a tick-infested area, it seemed probable that some of the bites had been by ticks.

Physical examination revealed a prostrated man with a temperature of 103°F, multiple insect bites over the entire

to be characteristic of the disease, especially in cases with a definite primary lesion. Convalescence is prolonged. The agglutination test is considered the most reliable diagnostic test for tularemia.

Some representative cases of the various types of tularemia encountered in this series of 50 cases are reported.

FIGURE 2 Case 4

The interpretations of these x-ray films were as follows: A (10-12-43) "There is an area of consolidation in the left upper lobe in the region of the second and third interspaces that resembles a lobar pneumonia" (this film was made in a field hospital with field equipment at a distance less than 72 inches, which explains the distortion of the cardiac shadow); B (10-17-43) "There remains a considerable amount of infiltration in the same area, with a small area of decreased density lying just above the end of the second rib, which appears to be cavitation"; C (2-7-44) "The lung fields have almost cleared. Only a small fibrotic area at the end of the second rib remains."

trunk and extremities, consolidation of the upper lobe of the left lung and moist rales over the lower lobe of the right lung. A roentgenogram of the thorax showed a diffuse infiltration in the upper left lobe (Fig. 2A).

On the 5th day, the temperature was 99.4°F, and it continued intermittently at this level for 7½ months. The blood agglutination titer for tularemia was 1:2560 on November 6 and 1:640 on January 7, 1944. After 225 days of hospitalization, the patient still complained of weakness, malaise and slight discomfort in the left upper chest. Serial roentgenograms revealed a gradual clearing of the pneumonic process in the left upper lobe. At the end of 7½ months, however, it was still undetermined whether this area represented a continued infiltrative process or fibrotic changes (Fig. 2C).

mears Anaerobic cultures revealed little of significance

The dosage of penicillin and the methods of administration are shown in Table 1. The intramuscular doses were given in a concentration of 1000 units per cubic centimeter of physiologic saline solution. In all the intratracheal cases except Case 7 the penicillin was administered by the supraglottic method preceded by topical cocaine. In Case 7, an intrabronchial catheter was used for three days and an intratracheal catheter for nine days but otherwise the usual supraglottic route was utilized. During all these intratracheal instillations the patient was placed so that the drug could reach the affected lobes. Each dose was dissolved in 10 to 20 cc of saline solution. The inhalation method consisted in nebulization of the penicillin solution in a vaporizer. The technic employed was that previously described.⁹ In the Otisville cases, however, a glass Y connection was placed on the tube leading from the oxygen tank to the

Of the 10 patients with a foul sputum, in 9 the odor completely cleared and in 1 it slightly diminished. The former effect was achieved within one day in 4 patients — intratracheal administration in 2, inhalation in 1, and intramuscular and intratracheal administration in 1, within forty-eight hours in 3 cases — intramuscular administration, intratracheal injection, and intratracheal injection and inhalation each in 1, and after intervals of three and six days the 2 other cases — (inhalation in 1 and intratracheal administration and inhalation in 1). Whenever the offensive smell of the sputum disappeared after penicillin, the effect continued throughout the period of therapy. In 3 cases the treatment is still being continued. The odor returned following discontinuation of penicillin in 3 patients after intervals of three days, four days and three months, respectively. Two patients had no recurrence of odor but the followup lasted for only eight days in one and one month in the other. Sufficient time has not elapsed to deter-

TABLE 2 *Changes in Amount of Sputum after Penicillin Therapy*

CASE NO	METHOD OF ADMINISTRATION	BEFORE PENICILLIN AMOUNT	AFTER PENICILLIN		SPUTUM LEVEL AFTER CESSATION OF TREATMENT
			AMOUNT	RAPIDITY OF EFFECT	
1	Intramuscular and intratracheal injection	160-240 cc	4 cc	6 days	60 cc (2 mo) 120 cc (3½ mo)
2	Intramuscular injection	60 cc	18 cc	2 days	Patient left against advice
3	Intratracheal injection	45-60 cc	22 cc	5 days	15 cc (3 wk) 30 cc (1 mo and 3 mo)
4	Intratracheal injection	100 cc	0 cc	3 days	40 cc (1 wk) 70 cc (3 and 4 wk)
5	Intratracheal injection	90 cc	40 cc	4 days	42 cc (6½ mo)
6	Intratracheal injection	120 cc	40 cc	4 days	80 cc (1 wk) 55 cc (3 wk and 6½ mo)
7	Intratracheal injection	207 gm	10 cc	4 wk	No followup
8	Inhalation	29 gm	11 gm	4 wk	20 gm (4 mo)
9	Inhalation	14 cc gm	0 gm	4 wk	79 gm (8 days)
10	Intratracheal injection and inhalation	180-240 cc	16 cc	5 days	Treatment continued
11	Intratracheal injection and inhalation	70 cc	14 cc	9 wk	Treatment continued
12	Inhalation	110 cc	23 cc	4 days	Treatment continued
			10 cc	6 wk	
			28 cc	6 days	Treatment continued
			12 cc	7 wk	

vaporizer and controlled by the patient's closing or opening the open end with his finger. When the connection was open, the oxygen passed through the Y tube to the outside and not to the nebulizer and the patient was able to rest. When it was closed, the oxygen passed to the vaporizer forming a penicillin mist or vapor, which was inhaled. An L-shaped glass extension was also connected to the stem of the vaporizer, which dipped down behind the base of the tongue so that the penicillin spray could be directed toward the larynx. Each dose was dissolved in 2 to 4 cc of saline solution.

There were no real difficulties in administering the drug. Three of the patients receiving intratracheal administration (Cases 4, 5 and 6) experienced slight nervousness and sleeplessness as the result of the cocaine. Use of the intrabronchial catheter was soon discontinued, since it appeared to be irritating. In 1 patient (Case 8) treated with inhalation therapy, a dermatitis occurred on the face and lips. This was relieved by a vaseline ointment without discontinuation of therapy. A skin test and a patch test with penicillin were both negative.

mine the lasting effect of the drug in these cases. One patient left the hospital against advice, and there is no information on the present status of his sputum.

The changes in the sputum volume are shown in Table 2. The figures covering the penicillin effect on the total twenty-four-hour sputum amount represent the lowest sputum level that was steadily maintained and the time during the period of treatment at which it occurred. Actually there was a progressive diminution in sputum output, which started as soon as treatment was begun, but the maximum reduction took place at variable periods after the treatment was initiated. As indicated by the table, this required from a few days to several weeks. The patients treated by intratracheal instillation in all cases but 1 showed the maximum effect within a few days. The inhalation cases and those with combined intratracheal injection and inhalation treatment showed a significant early reduction, but the most marked diminution required several weeks. In every patient but the one who left against advice, the sputum reduction was at least 50 per cent. For

action of the penicillin is exerted chiefly on the former, their presence or absence in the smear constituted a practical index of the effectiveness of the penicillin, the reliability of which was borne out by the occasional cultures. In 8 patients, bioassays of the penicillin content of the sputum, urine and blood were frequently done — in some cases daily — during and after the administration of the drug and were continued until it disappeared from the specimens. The method described by Woolley and Schmidt,⁸ an adaptation of the Fleming agar-hole method, was employed. With this procedure, contaminated material can be readily assayed and blood serums measured. Although the sensitivity of the test organism (*Staphylococcus aureus* "H")

lobe was involved in 12 cases, the right lower lobe in 9, and the right middle lobe and lingula portion of the left upper lobe in 6 each. Of the thirty-three bronchiectatic lobes, a marked saccular condition was present in nineteen, a moderate saccular involvement in three, moderate cylindrical and varicose dilatations in six, and slight cylindrical enlargement in five. In addition, bronchiectasis existed in two lobes that were atelectatic.

The onset of symptoms followed pneumonia in 10 cases, pertussis in 1 and influenza in 1. The symptoms had existed for four to twenty-four years, with a duration of more than ten years in all but 2 cases. In 7 cases, pneumonic episodes had recurred, and in 2 of these they had done so two and

TABLE 1 Dosage and Method of Treatment

CASE No	METHOD OF ADMINISTRATION	DURATION OF TREATMENT days	DOSAGE	TOTAL DOSAGE units
1	Intramuscular and intratracheal injection	12	100,000 units a day 80,000 intramuscularly (10,000 every 3 hours) and 20,000 intratracheally	1,200,000
3	Intramuscular injection	5½	100,000 units a day alternating 10,000 and 15,000 every 3 hr	550,000
2	Intratracheal injection	10	100,000 units a day 50,000 twice daily	1,000,000
4	Intratracheal injection	4	250,000 units a day 100,000 in morning, 150,000 in afternoon	1,000,000
5	Intratracheal injection	4	250,000 units a day 100,000 in morning, 150,000 in afternoon	1,000,000
6	Intratracheal injection	4	250,000 units a day 100,000 in morning, 150,000 in afternoon	1,000,000
7	Intratracheal injection	30	50,000 units a day	1,500,000
8	Inhalation	30	50,000 units a day 10,000 every 3 hours for five doses	1,500,000
9	Inhalation	60	100,000 units a day for first 20 days 20,000 every 3 hours for 5 doses, then 50,000 units a day for 40 days 10,000 every 3 hours for five doses	4,000,000
10*	Intratracheal injection and inhalation	105	100,000 units a day intratracheally for 10 days then 100,000 units three times a week by inhalation (100,000-unit doses) for 95 days	4,900,000*
11*	Intratracheal injection and inhalation	115	100,000 units a day intratracheally for 10 days then 100,000 units three times a week by inhalation (100,000-unit doses) for 105 days	5,500,000*
12*	Inhalation	60	100,000 units a day for 10 days then 100,000 units three times a week	3,100,000*

*Patient still under treatment

employed in this method is insufficient to determine accurately amounts less than 0.2 units per cubic centimeter, the method was considered adequate because penicillin in lower concentrations is ineffective against some organisms — staphylococci and so forth. From necessity, containers for sputum and urine were kept refrigerated at all times in ice buckets near the patients' beds so that as little of the penicillin effect as possible would be lost. The amount of active penicillin per cubic centimeter for each specimen was determined, and from this the twenty-four-hour elimination was estimated.

RESULTS

The diagnosis was made in every case by means of a bronchogram with lipiodol. The bronchiectasis was multilobar in all 12 cases and bilateral in 11. Two lobes were involved in 4 cases, three in 7, and four in 1. In other words, the 12 patients had thirty-three bronchiectatic lobes. The left lower

lobe was involved in 12 cases, the right lower lobe in 9, and the right middle lobe and lingula portion of the left upper lobe in 6 each. Of the thirty-three bronchiectatic lobes, a marked saccular condition was present in nineteen, a moderate saccular involvement in three, moderate cylindrical and varicose dilatations in six, and slight cylindrical enlargement in five. In addition, bronchiectasis existed in two lobes that were atelectatic.

The onset of symptoms followed pneumonia in 10 cases, pertussis in 1 and influenza in 1. The symptoms had existed for four to twenty-four years, with a duration of more than ten years in all but 2 cases. In 7 cases, pneumonic episodes had recurred, and in 2 of these they had done so two and

three times, respectively, only 1 patient had a co-existent tuberculosis, and in this case it had been present in both upper lobes for six years. The symptoms and physical findings were those characteristic of this condition. In addition, 2 cases gave radiographic evidence of sinus involvement. The sputum showed varying degrees of purulence. In all but 2 cases it had a foul odor and in most cases it separated on standing into the characteristic three layers. All the specimens exhibited a more or less similar bacterial flora. The more putrid they were, the greater were the number of organisms. Gram-positive organisms predominated in all smears: chains (streptococci) were present in 9 patients, grape-like clusters (staphylococci) in 8, diplococci in 8 and rods in 2. The gram-negative organisms included fusiform bacilli in 5 patients, biscuit-shaped diplococci (*Micrococcus catarrhalis*) in 4, rods in 3, cocci in 2, and diplococci in 1. No spirochetes were found with the Fontana stain. The sputum cultures verified the findings of the sputum

years Anaerobic cultures revealed little of significance

The dosage of penicillin and the methods of administration are shown in Table 1. The intramuscular doses were given in a concentration of 100 units per cubic centimeter of physiologic saline solution. In all the intratracheal cases except Case 7, the penicillin was administered by the supraglottic method, preceded by topical cocaine. In Case 7, an intrabronchial catheter was used for three days and an intratracheal catheter for nine days, but otherwise the usual supraglottic route was utilized. During all these intratracheal instillations the patient was placed so that the drug could reach the affected lobes. Each dose was dissolved in 10 to 20 cc of saline solution. The inhalation method consisted in nebulization of the penicillin solution in a vaporizer. The technique employed was that previously described.² In the Otisville cases, however, a glass Y connection was placed in the tube leading from the oxygen tank to the

Of the 10 patients with a foul sputum, in 9 the odor completely cleared and in 1 it slightly diminished. The former effect was achieved within one day in 4 patients — intratracheal administration in 2, inhalation in 1 and intramuscular and intratracheal administration in 1, within forty-eight hours in 3 cases — intramuscular administration, intratracheal injection, and intratracheal injection and inhalation each in 1, and after intervals of three and six days the 2 other cases — (inhalation in 1 and intratracheal administration and inhalation in 1). Whenever the offensive smell of the sputum disappeared after penicillin, the effect continued throughout the period of therapy. In 3 cases the treatment is still being continued. The odor returned following discontinuation of penicillin in 3 patients after intervals of three days, four days and three months, respectively. Two patients had no recurrence of odor, but the followup lasted for only eight days in one and one month in the other. Sufficient time has not elapsed to deter-

TABLE 2 Changes in Amount of Sputum after Penicillin Therapy

CASE NO	METHOD OF ADMINISTRATION	BEFORE PENICILLIN	AFTER PENICILLIN		SPUTUM LEVEL AFTER CESSATION OF TREATMENT
		AMOUNT	AMOUNT	RAPIDITY OF EFFECT	
1	Intramuscular and intratracheal injection	160-240 cc	45 cc	6 days	60 cc (2 mo) 120 cc (3½ mo)
2	Intramuscular injection	60 cc	18 cc	2 days	Patient left against advice
3	Intratracheal injection	45-60 cc	22 cc	5 days	15 cc (3 wk) 30 cc (1 mo and 3 mo)
4	Intratracheal injection	300 cc	90 cc	1 day	40 cc (1 wk) 70 cc (3 and 4 wk)
5	Intratracheal injection	90 cc	40 cc	4 days	42 cc (6½ mo)
6	Intratracheal injection	120 cc	40 cc	4 days	80 cc (1 wk) 55 cc (3 wk and 6½ mo)
7	Intratracheal injection	207 gm	108 gm	4 wk	No followup
8	Inhalation	29 gm	11 gm	4 wk	20 gm (4 mo)
9	Inhalation	145 gm	50 gm	4 wk	79 gm (8 days)
10	Intratracheal injection and inhalation	180-240 cc	36 cc	5 days	Treatment continued
			14 cc	9 wk	
11	Intratracheal injection and inhalation	70 cc	23 cc	4 days	Treatment continued
			10 cc	6 wk	
12	Inhalation	110 cc	28 cc	6 days	Treatment continued
			12 cc	7 wk	

vaporizer and controlled by the patient's closing or opening the open end with his finger. When the connection was open, the oxygen passed through the Y tube to the outside and not to the nebulizer and the patient was able to rest. When it was closed, the oxygen passed to the vaporizer, forming a penicillin mist or vapor, which was inhaled. An L-shaped glass extension was also connected to the stem of the vaporizer, which dipped down behind the base of the tongue so that the penicillin spray could be directed toward the larynx. Each dose was dissolved in 2 to 4 cc of saline solution.

There were no real difficulties in administering the drug. Three of the patients receiving intratracheal administration (Cases 4, 5 and 6) experienced slight nervousness and sleeplessness as the result of the cocaineizations. Use of the intrabronchial catheter was soon discontinued, since it appeared to be irritating. In 1 patient (Case 8) treated with inhalation therapy, a dermatitis occurred on the face and lips. This was relieved by a vaseline ointment without discontinuation of therapy. A skin test and a patch test with penicillin were both negative.

mine the lasting effect of the drug in these cases. One patient left the hospital against advice, and there is no information on the present status of his sputum.

The changes in the sputum volume are shown in Table 2. The figures covering the penicillin effect on the total twenty-four-hour sputum amount represent the lowest sputum level that was steadily maintained and the time during the period of treatment at which it occurred. Actually there was a progressive diminution in sputum output, which started as soon as treatment was begun, but the maximum reduction took place at variable periods after the treatment was initiated. As indicated by the table, this required from a few days to several weeks. The patients treated by intratracheal instillation in all cases but 1 showed the maximum effect within a few days. The inhalation cases and those with combined intratracheal injection and inhalation treatment showed a significant early reduction, but the most marked diminution required several weeks. In every patient but the one who left against advice, the sputum reduction was at least 50 per cent. For

the entire group, excluding those still under treatment, the average was 63 per cent. It is possible that the postural drainage itself accounted for some diminution in sputum. The best effect has thus far been shown in patients receiving combined intratracheal injection and inhalation therapy. In the patients followed up for periods averaging over three months, however, cases with an increase in sputum output occurred after treatment was discontinued. In 2 of the cases with intratracheal administration, the sputum continued to diminish for a short time (one to three weeks) before it increased. In no case did it return to its original level present before therapy, and usually it continued at only half of the pretreatment amount. Since postural drainage and the collection of sputum cannot be so well controlled after discharge from the institution, the expectoration may have been greater than that reported by the patients.

As would be expected, the penicillin tended to clear the sputum of organisms, especially the gram-positive ones, with rapidity. As a result of this, the pus cells were materially reduced. In 7 cases, all gram-positive organisms disappeared completely from the sputum. This was achieved by every method of administration, except in the patient given penicillin intramuscularly who left against advice. In the intratracheally treated cases, this effect occurred within two or three days, whereas in those treated by inhalation it required a week or two. In 3 patients, the gram-positive bacteria were eliminated within one or two weeks, but a few reappeared while treatment was continued. In 2 cases, including that of the patient incompletely treated, occasional gram-positive organisms remained.

Gram-negative organisms were also favorably influenced by the treatment. In 4 cases, — 3 treated intratracheally and 1 by inhalation, — they disappeared. With the intratracheal injection, this occurred within two to four days, and with inhalation at the end of two weeks. In the other cases a rare or occasional number of gram-negative organisms persisted.

In every case there was a decrease in the purulence of the sputum, and usually only a few cells remained. As with the bacterial changes, the intratracheal injection produced the maximum effect in a few days, and inhalation technic in one or two weeks.

In all patients followed up, there was a rapid change in the bacterial content and purulence of the sputum as soon as the penicillin was discontinued. In 5 of the 8 patients with a completed course of treatment, gram-positive organisms appeared or increased within two to five days after the penicillin was stopped and continued to multiply. In 3 cases, — all treated intratracheally, — the organisms appeared or increased after an interval of one or two weeks and later became more numerous. In 6 patients, gram-negative organisms re-

appeared or increased, either in a few days or a few weeks.

In every case the sputum also became more purulent when the penicillin was stopped. This took place either within a few days or after a week or two.

There was symptomatic improvement in every patient. Cough was rapidly alleviated, and in all but 2 patients the effect became evident within a few days. The cough decreased to the point where expectoration took place with postural drainage only. Night coughing almost ceased, and the stimulation to cough formerly caused by exertion, laughter, deep breathing or change in position no longer occurred. Dyspnea was much reduced, and in 1 patient it was eliminated. Wheezing and chest heaviness were also relieved. Anorexia was improved. Six patients gained weight while under treatment, and 4 of these continued to do so after penicillin was discontinued. Significantly, several of these patients had been markedly under weight for many years. Two of the patients began to gain after treatment. A slight loss of weight occurred in 3 patients, 2 of whom had had a normal weight before admission. One patient showed a marked reduction in nasal discharge. Incidentally, in 1 case with a pustular acne of the face the condition entirely cleared with treatment, although the skin lesions reappeared after penicillin was discontinued. The 1 patient who had tuberculosis and bronchiectasis had blood-streaked sputum for two days in the first week of treatment, expectorated about 15 cc of blood twelve days after penicillin was initiated and also had blood-streaked sputum for several days during the third week of treatment; he had, however, had similar symptoms before — severe hemoptysis on two occasions one year previously, with streaking over a period of three or four weeks. There has not been a sufficiently long follow-up period to determine the duration of the symptomatic benefits. It was noted, however, that cough and expectoration again increased but that the general well-being continued after cessation of therapy.

In 7 patients, there was a change in physical signs, with the chest appearing clearer, owing to a decrease in the amount of moisture. The white-cell counts and sedimentation rates revealed no significant changes during treatment, except in 1 case, in which a marked diminution in leukocytosis occurred.

The assay studies revealed the following results. With intramuscular penicillin (Case 3), only once was the drug found in the sputum. This was on the first full day of treatment, and the assay showed 0.4 units per cubic centimeter. That there was good systemic absorption was indicated by blood levels of 0.2, 0.3 and 0.4 units per cubic centimeter and the presence of considerable penicillin in the urine. The lack of penicillin in the sputum of patients receiving intramuscular treatments was also found by White et al.⁷

The first patient treated intratracheally alone (Case 2) received 1,000,000 units in ten days. A very high penicillin titer was found in the sputum, with an average of 284 units per cubic centimeter, which assured an excellent topical or bronchial effect. The penicillin was given in a selective manner by instillation in the diseased lobes. That excellent pulmonary absorption occurred was indicated by the high blood and urine levels, with probable good parenchymal effect. The urine concentration averaged 38 units per cubic centimeter, which meant that over 30 per cent of the total dose given was recovered in the urine. The blood levels were 0.4, 0.5 and 0.6 units per cubic centimeter. Penicillin was recovered from the sputum for eight days and from the urine for three days after treatment was discontinued.

The next three intratracheally treated patients (Cases 4, 5, and 6) received 1,000,000 units in four days. Extremely high concentrations of penicillin were found in the sputums, with an average of 331, 552 and 159 units per cubic centimeter, respectively. The low level in the last patient was due to the fact that the administration of the drug was somewhat difficult and that not all of it reached the lung. The urine concentration averaged 38, 19 and 36 units per cubic centimeter, respectively. In 2 cases the blood level did not rise above 0.1 units per cubic centimeter, and in 1 case it reached 0.25 and 0.45 units. In these patients penicillin was found in the sputum for no longer than 3 days and in the urine for no longer than two days after treatment was stopped.

Although an extremely high sputum concentration of penicillin was obtained for a short time, this method of rapid intensive administration had several significant disadvantages. A penicillin concentration in the sputum beyond an optimum level, or one adequate to control the bronchial and parenchymal infection, is undesirable because the excess penicillin is lost in the expectoration. The amount of penicillin absorbed through the lung is indicated by the concentration in the urine and blood. The penicillin levels in the urine and blood of these 3 patients were lower than that found in the patient given the same dose over a period of ten days instead of four days. Penicillin was also found for a shorter time in these patients after the treatment was stopped. Because of this, it was decided to utilize the penicillin in the form of a smaller dose and to administer it over a longer period.

The next patient (Case 7) received 50,000 units intratracheally for thirty days, a total dosage of 1,500,000 units. The assay studies revealed an average sputum concentration of 101 units per cubic centimeter, a urine level of 8.3 units and a blood concentration of 0.1 to 0.25 units. These concentrations were less than those found in the patients given penicillin intratracheally for four to ten days. The results of treatment were not so

good as in the patient with ten days of therapy. The hoped-for benefit of prolongation of treatment for thirty days was apparently offset by the fact that the dosage was too small. Moreover, daily intratracheal instillations for more than a short period are definitely undesirable. It was therefore decided to use penicillin by inhalation, since this is an extremely simple method of administration. Our⁹ previous experience with nebulization had indicated that drugs so given penetrate the lung, provide a topical effect and diffuse into the blood stream.

The first patient treated by inhalation (Case 8) received 1,500,000 units in thirty days (50,000 units daily). The penicillin concentration in the sputum was quite low and, although it varied greatly, averaged only 13 units per cubic centimeter — a lower concentration than that in any of the other patients except the one given intramuscular injections. The urine concentration, 1.8 units, was also the lowest in any patient. Assay of the blood showed no penicillin present on three occasions and 0.1 and 0.2 units per cubic centimeter at two other times. These low concentrations indicate that not all the penicillin vaporized enters the lungs. A certain portion reaches the buccal mucosa, pharynx and esophagus and is swallowed with the saliva. Yet with the concentration of penicillin noted in this case, a good clinical and bacteriologic effect was evident.

It was decided that a larger dose was needed to build up a higher concentration in the bronchi and that the administration should be continued for a longer period of time. The next patient treated by inhalation (Case 9) received 4,000,000 units in sixty days. The penicillin concentration in the sputum varied greatly but was maintained at a fairly high average level (86 units per cubic centimeter). This proved that inhalation in proper dosage could result in a favorable topical effect in the bronchi. The urine concentration averaged only 2 units per cubic centimeter, however, and three blood specimens failed to reveal any penicillin. These figures when compared with those in the intratracheal injection cases show that with inhalation there was much less bronchial and pulmonary absorption of penicillin. No assay studies were done in the last 3 patients treated at St. Clare's Hospital.

Two patients have had no follow-up, and 3 are still being treated. Of the other 7 patients, 2 were seen a month after treatment was stopped, 1 was followed for three months, 2 were followed for three and a half to four months, and 2 were followed for six and a half months.

DISCUSSION

Boyd¹⁰ in describing bronchiectasis states

There is a combination of inflammation and degradation of tissue. The wall of the bronchus is congested and

infiltrated with chronic inflammatory cells. The mucous membrane is atrophic and the epithelium may be completely absent in places. In advanced cases, various elements of the bronchial wall, the glands, the muscle and the elastic tissue may have more or less disappeared and be replaced by dense fibrous tissue.

Hinshaw and Schmidt¹¹ write

If one reviews the pathologic picture of true bronchiectasis one sees how difficult it is for nature to repair such damage. There has been extensive destruction of irreplaceable structures in the walls of important bronchi with resultant functional impairment of the air channels and accumulation and putrefaction of secretion which lead to further destruction and greater functional impairment.

The destructive changes of bronchiectasis are irreversible but the findings in the present series point to possibilities for the control of bronchiectasis. This study has shown that extremely favorable results can be achieved in the treatment of bronchiectasis with penicillin. Although the sputum was not entirely eliminated, a great diminution in expectoration occurred. It was demonstrated that the extremely foul sputum odor could be removed, organisms practically eliminated, and purulence greatly reduced. Intratracheal penicillin produced the latter two effects within a few days, and inhalation produced them in one or a few weeks. Symptomatic improvement, invariably of considerable degree, also took place. When treatment was discontinued, expectoration increased, organisms reappeared, pus cells became more numerous, and in many cases the odor returned. The sputum level was below the original one, and much of the symptomatic improvement persisted. These findings indicate that the results of treatment can be properly judged only after a long follow-up period and not by immediate changes alone.

It is generally accepted that the only cure for bronchiectasis is lung resection. Most, if not all, of the patients in this series, however, could not be treated surgically because of multilobar and bilateral involvement, and instead received palliative or symptomatic treatment. Moreover, all but the last 3 patients had only a short temporary course of treatment.

We wish to emphasize that while the penicillin was administered and for some time thereafter, excellent results were obtained, which represent a definite accomplishment in the treatment of bronchiectasis. A method has been demonstrated that can also be used in the preoperative preparation of patients for lung resection. With the expectoration markedly diminished and the sputum free of organisms, it is believed that the bronchiectatic lung can be handled during operation with little danger of aspiration into healthy pulmonary tissue and with diminished chances of an empyema should a bronchial fistula occur.

If the subjective and objective improvements obtained by our patients while on penicillin can be indefinitely continued by prolongation of treatment, a form of therapy is available in nonsurgical cases with marked advantages not present in other

nonoperative methods. This therapy requires the use of penicillin for an extremely long period, and perhaps indefinitely, somewhat in the manner that insulin must be constantly taken to control diabetes. The last 3 patients in this series are still being treated after intervals as long as sixteen weeks, and the penicillin will be continued. Because of the sustained effectiveness of continued therapy, although no cure may occur, it seems likely that the progressive and irreversible progress of the condition to chronic invalidism and death can be interrupted. Possibly the occurrence of pulmonary complications — bronchitis, pneumonia, lung abscesses and empyema — and the general consequences of bronchiectasis — amyloidosis, cardiac failure and brain abscesses — can also be reduced or prevented. The control of the bronchiectatic condition is of particular value during the winter months when pulmonary complications are rife. It is also possible under this treatment to remove the "psychic, social, economic and physical handicaps" of bronchiectasis.

Heretofore no therapy has been available that could control the bronchial and pulmonary infection of bronchiectasis. Penicillin has definitely curtailed the evidences of suppuration in our cases. It is within the range of possibility that penicillin in sufficient dosage and administered for a long enough period may eliminate the bacterial infection and abolish the expectoration and that repair may ensue. Although this program may be utopian, our findings indicate that the further use of penicillin is well justified.

Studies are now under way to determine the precise dose and length of treatment that will achieve the best results. Intramuscular injection therapy is not being employed because of the negligible amount of penicillin obtained in the bronchial secretions and the discomfort of repeated injections. The intratracheal route gives the most effective local concentration of the drug combined with a high absorption rate. For the treatment of bronchiectasis, penicillin is required over a long period, and it is not advisable to have daily intratracheal instillations or intrabronchial catheterizations for so long a time. There are the difficulty of anesthesia, the presence of sensitivity to cocaine and the possibility of reaction from manipulation with a bronchial catheter, as occurred in Case 7. A short intensive course with intratracheal instillations of at least 100,000 units daily is, however, suggested as suitable for preoperative preparation for lung resection because of bronchiectasis. This method can also provide an immediate maximum and rapid effect prior to continuation of penicillin by inhalation, as was done in Cases 10 and 11. Repeated short courses may also be of value.

Penicillin inhalation is effective, and when given in proper dosage provides an excellent bronchial concentration and parenchymal absorption. The inhalation method is, moreover, the simplest pro-

edure of any available. There is somewhat of a loss in its administration, however, and not all the drug reaches the lungs. For a result comparable to that achieved with intratracheal instillation, much more penicillin has to be used, but the increasing availability of the drug and its lowered cost warrant the use of this method. Inhalation is not necessarily a hospital procedure and is easily applied either in the physician's office, the clinic or the patient's home. The vaporizer is extremely easy to employ with an oxygen tank or by hand, although the latter method is the more difficult of the two. Experience has shown that patients can easily be taught to utilize a vaporizer and oxygen tank at home, and this has been done in the treatment of chronic pulmonary emphysema.¹² Penicillin can be used in this manner over a long period of time, since there are no evidences of toxicity.

It is desirable to treat adequately the sinusitis that is often present in patients with bronchiectasis. This reduces the possibility of drainage of purulent material from the sinuses to the respiratory tract.

In using the treatment described on a long-term basis, one must also take into consideration the possibility that the organisms will in time show resistance to the penicillin. In 3 of our cases, a few organisms reappeared during treatment. Treatment over a much longer period is required to gain definite information on this point. Gallardo¹³ studied 112 cases of traumatic wounds of the extremities and draining abscesses and determined the naturally resistant and fast strains of staphylococci, both pathogenic and nonpathogenic. Nine and four tenths per cent of these organisms acquired resistance to the penicillin, and 12.4 per cent had natural resistance. The exact period at which the organisms became fast was not known, but differences of five to forty days were noted. Gallardo considers it advisable to assay routinely the sensitivity of bacteria from infected foci in all patients in whom penicillin is contemplated or in progress. Demerec¹⁴ studied the production of strains of staphylococcus resistant to various concentrations of penicillin, and found that such strains could be obtained by growing the bacteria on mediums containing increasingly higher concentrations of the drug. Resistance was not induced or acquired through interaction between the bacteria and the penicillin, but appeared as an inherited characteristic that originated through mutation. The development of penicillin-resistant staphylococci during therapy has been attributed to the use of sublethal concentrations of the drug and is considered of little clinical significance.¹⁵

This question of resistance of organisms is still an unsettled one and its relationship to therapy is yet to be determined.

SUMMARY

A report is made of 12 cases of severe bronchiectasis treated with penicillin.

The drug was administered by intramuscular injection, intratracheal injection and inhalation and combinations of these.

The total dosage of penicillin varied from 550,000 to over 5,500,000 units, and the length of treatment from four to one hundred and fifteen days. In 3 cases, therapy is still being continued.

The concentration of penicillin in the sputum was highest with intratracheal administration, less with inhalation and lowest with intramuscular injection.

The most rapid results were achieved with intratracheal instillations.

The simplest method of administration is inhalation.

Remarkable results were achieved with treatment. The sputum was considerably diminished and its odor was removed, most organisms were eliminated, and purulence was reduced. Considerable symptomatic improvement also took place. These changes were maintained while the penicillin was continued but did not long persist when it was stopped.

As symptomatic therapy for nonoperative cases and possibly for the control of bronchiectasis, penicillin will be required over a long period of time and perhaps indefinitely.

Penicillin given intratracheally and by inhalation is also suggested as a form of preoperative preparation for lung resection for bronchiectasis.

The results justify the further investigation of the use of penicillin in the treatment of bronchiectasis.

The control of the bronchiectatic condition is of particular value during the winter months when pulmonary complications are rife. It is also possible under this treatment to remove the "psychic, social, economic and physical handicaps" of bronchiectasis.

Heretofore no therapy has been available that could control the bronchial and pulmonary infection of bronchiectasis. Penicillin has definitely curtailed the evidences of suppuration in our cases. It is within the range of possibility that penicillin in sufficient dosage and administered for a long enough period may eliminate the bacterial infection and abolish the expectoration and that repair may ensue. Although this program may be utopian, our findings indicate that the further use of penicillin is well justified.

Studies are now under way to determine the precise dose and length of treatment that will achieve the best results. Intramuscular injection therapy is not being employed because of the negligible amount of penicillin obtained in the bronchial secretions and the discomfort of repeated injections. The intratracheal route gives the most effective local concentration of the drug combined with a high absorption rate. For the treatment of bronchiectasis, penicillin is required over a long period, and it is not advisable to have daily intratracheal instillations or intrabronchial catheterizations for so long a time. There are the difficulty of anesthesia, the presence of sensitivity to cocaine and the possibility of reaction from manipulation with a bronchial catheter, as occurred in Case 7. A short intensive course with intratracheal instillations of at least 100,000 units daily is, however, suggested as suitable for preoperative preparation for lung resection because of bronchiectasis. This method can also provide an immediate maximum and rapid effect prior to continuation of penicillin by inhalation, as was done in Cases 10 and 11. Repeated short courses may also be of value.

Penicillin inhalation is effective, and when given in proper dosage provides an excellent bronchial concentration and parenchymal absorption. The inhalation method is, moreover, the simplest pro-

A perceptible increase in the size of the heart was observed in only a small number of patients while they were under observation. In most of these cases the enlargement was slight, unless complicated by acute pericarditis with effusion. Frequently, however, the first sound at the mitral area became muffled or diminished in intensity. In most cases a soft, blowing systolic murmur developed at the mitral area. In many of these patients it became audible over the entire precordium, and in some it became loud and harsh and was transmitted to the axilla. The systolic murmurs varied in intensity and degree of transmission from time to time and often disappeared when the patient was in the sitting position.

A low-pitched, rumbling, mid-diastolic murmur appeared at the mitral area in a number of patients. It usually developed after two to three months of hospitalization, but was observed as early as three weeks after admission, raising the question of a pre-existing mitral lesion, notwithstanding the patient's denial of antecedent rheumatic infection. This murmur was best elicited during forced expiration with the patient lying in the left oblique position. In 5 cases, — none with aortic insufficiency, — it was transitory and disappeared within four weeks.

In the minority of cases, the aortic second sound became slurred and a soft, blowing diastolic murmur appeared at the left third and fourth interspaces near the sternum. In 8 patients, the murmur ultimately disappeared. In the others, it persisted and frequently became louder, longer in duration and more widely transmitted and was eventually associated with peripheral signs of aortic incompetency.

Signs of acute pericarditis were observed in 19 cases. It is noteworthy that only in these patients did pleurisy, with or without effusion, and pneumonia develop. In 5 cases, signs of pericardial effusion were elicited.

The spleen was slightly enlarged in 5 cases.

Skin lesions, when present, were usually those of erythema multiforme, but in some cases small ecchymotic areas were noted at the site of the affected joints, spreading to involve the other parts of the extremities. Subcutaneous nodules were not found in any patient of this series.

Rapid loss of weight, amounting to as much as 16 to 20 pounds, was almost invariably noted during the acute stage of the illness.

Electrocardiographic changes were observed in 63 per cent of the patients, often after only a few days of illness. These occurred with increasing frequency when serial electrocardiographic studies were made. The most frequent abnormality was prolongation of the auriculoventricular conduction time, the longest PR interval being 0.62 second. In a number of cases, although the PR intervals were within the range of normal (0.12 to 0.21 second), repeated electrocardiograms showed variations in excess of 0.02 second. These variations were inter-

preted as being significant of first-degree auriculoventricular block. They emphasize the importance of frequent electrocardiographic tracings in the same patient. All degrees of auriculoventricular block were observed, and occasionally that of the indeterminate type was seen. At times the QRS complexes were inverted and notched in Lead CF₄, and the ST segments were either elevated or depressed beyond normal in one or more leads. The T waves often became tiny, diphasic or inverted in one or more leads, especially in Lead CF₄. In the patients with physical signs of pericarditis, the T waves usually became inverted in the limb leads but the ST changes were slight. Premature systoles were frequently noted. Of the other arrhythmias, paroxysmal auricular tachycardia, auricular fibrillation and auricular flutter occurred in isolated cases. The occurrence of interference dissociation in 18 cases was of clinical interest, although of no pathological significance. This abnormality, ascribed to hyperirritability of the auriculoventricular node, occurred only during the acute stage of illness. The electrocardiographic changes were transient in almost all the cases, usually returning to normal within seven to twenty-one days but occasionally persisting for as long as five months. When right or left ventricular preponderance developed, it generally remained during the entire period of observation. It is noteworthy that the electrocardiographic abnormalities were more frequent and also more marked in the patients admitted to the hospital during the peak of the epidemic periods.

An increased sedimentation rate has generally been regarded as a constant finding in acute rheumatic fever. In the vast majority of cases our findings were in agreement with this observation, but in a small number of patients with mild joint involvement and electrocardiographic evidence of first-degree auriculoventricular block the sedimentation rate was repeatedly normal. Thus, the deduction may be drawn that a normal rate does not preclude the existence of active rheumatic fever.

The white-cell count usually showed a leukocytosis, ranging between 10,500 and 16,000. In the minority of patients, a mild hypochromic anemia was found. Albuminuria, pyuria and microscopic hematuria were frequently present on admission, they generally disappeared within several days.

COURSE

The course was variable, depending on the tenacity of the rheumatic infection. The great majority of patients recovered after a single bout of fever and ran a relatively benign course. In the others, either the acute stage was followed by a long period of low-grade activity or the remission was punctuated by a recrudescence of symptoms, usually subsequent to a hemolytic streptococcus infection of the upper respiratory tract. It is well recognized that the danger of disabling heart disease

THE CLINICAL ASPECTS OF RHEUMATIC FEVER IN ADULTS*

COMMANDER DAVID H. ROSENBERG (MC), USNR †

RHEUMATIC fever has been generally regarded as a disease principally affecting children, and its occurrence in adults has as a consequence been more or less ignored. The high incidence of this disease among members of the armed forces has, however, served to focus attention on its importance in older persons, particularly young adults. It is the purpose of this paper to present a composite picture of the clinical aspects of rheumatic fever as observed in a series of 1000 patients studied at a large naval hospital.

ETIOLOGY

Although the etiology of rheumatic fever remains unknown, epidemiologic studies indicate that there is a close relation between the disease and epidemics of Group A beta-hemolytic streptococcus infections. In almost all our patients, there was a recent history of an acute upper respiratory infection, such as coryza, sinusitis, pharyngitis, tonsillitis or otitis media, which occurred one to four weeks prior to the onset of rheumatic fever. In some cases, scarlet fever ushered in an attack of rheumatic fever. In 6 patients, acute polyarthritis and carditis appeared during the course of German measles, but whether these manifestations were due to the virus of that disease or were related to a previous unrecognized hemolytic streptococcus infection cannot be stated with certainty.

Exercise, fatigue and damp, rainy or cold weather were found to be provocative factors. As in many other acute infectious diseases, there was a distinct seasonal variation, with the highest admission rate from December to April, inclusive, when the disease reached epidemic proportions.

Contrary to expectations, in only 38 per cent of the patients was it possible to elicit an antecedent history of rheumatic fever, chorea, growing pains or heart trouble. In many cases there was a familial history of rheumatic fever suggesting a constitutional factor.

INCIDENCE

The ages ranged from seventeen to forty-one years, with most patients between seventeen and twenty-four. All but 5 patients were men, which may to a large measure be explained by the relatively small number of women on duty in the district from which these patients originated.

SYMPTOMS AND FINDINGS

The clinical manifestations were extremely varied. In most cases, the onset was marked by the appearance of acute arthritis, with pain, swelling, stiffness,

tenderness and often redness of one or more joints. The knees, ankles, wrists, elbows and small joints of the feet were those most frequently affected, although no joints escaped involvement. These symptoms were accompanied by malaise, lassitude, fatigue, tachycardia and fever ranging from 99 to 104°F, and were followed by similar involvement of other joints. Often the initial joint involvement persisted and the other joints successively became affected. The knee joints often became greatly distended with synovial fluid. Epistaxis was not infrequent, but drenching sweats were observed only rarely.

In many patients the clinical picture was less typical than the foregoing one, and it was occasionally bizarre. In some cases only mild pain and stiffness involving a single joint were noted, tachycardia, systemic manifestations and objective findings being absent. In many such cases, when the knees, ankle or foot were affected, the symptoms were misinterpreted as the result of a coincidental fall, sprain or even weak arches and were treated by immobilization. In other cases slight redness, mild tenderness and minimal swelling were encountered.

In one group of patients the only symptoms were vague muscular pains and stiffness. In another, chills and intermittent fever were the only complaints. Lumbar backache was frequent and was often accompanied by urinary frequency and the microscopic findings of pyelonephritis.

Of particular significance is the fact that the presenting symptoms were often abdominal, consisting of pain, with anorexia, nausea and vomiting and at times with diarrhea. Diffuse abdominal tenderness, with or without the rebound phenomenon, was usually found. In some of these cases the clinical picture simulated that of acute appendicitis, but a careful history and close observation revealed joint pain, tenderness and stiffness, followed by evidence of acute carditis.

In 15 cases, the principal symptoms were precordial pain and dyspnea, with or without cyanosis. In these cases the joint manifestations were minor and were generally disregarded by the patient. Various degrees of auriculoventricular block, sometimes extending to complete heart block with ventricular rates as low as 20 per minute, were found by electrocardiographic studies.

Cerebral manifestations, when present, were mild, consisting mainly of drowsiness and stupor. Rarely, transient psychoses with delirium were observed in the acutely ill patients with high fever. Choreia was present in only 3 patients. In 5 patients with stiffness and pain in the cervical vertebrae, meningitis was closely simulated.

†Associate in medicine, Northwestern University Medical School and adjunct attending physician, Michael Reese Hospital, Chicago (on leave of absence).

A perceptible increase in the size of the heart was observed in only a small number of patients while they were under observation. In most of these cases the enlargement was slight, unless complicated by acute pericarditis with effusion. Frequently, however, the first sound at the mitral area became muffled or diminished in intensity. In most cases a soft, blowing systolic murmur developed at the mitral area. In many of these patients it became audible over the entire precordium, and in some it became loud and harsh and was transmitted to the axilla. The systolic murmurs varied in intensity and degree of transmission from time to time and often disappeared when the patient was in the sitting position.

A low-pitched, rumbling, mid-diastolic murmur appeared at the mitral area in a number of patients. It usually developed after two to three months of hospitalization, but was observed as early as three weeks after admission, raising the question of a pre-existing mitral lesion, notwithstanding the patient's denial of antecedent rheumatic infection. This murmur was best elicited during forced expiration with the patient lying in the left oblique position. In 5 cases, — none with aortic insufficiency, — it was transitory and disappeared within four weeks.

In the minority of cases, the aortic second sound became slurred and a soft, blowing diastolic murmur appeared at the left third and fourth interspaces near the sternum. In 8 patients, the murmur ultimately disappeared. In the others, it persisted and frequently became louder, longer in duration and more widely transmitted and was eventually associated with peripheral signs of aortic incompetency.

Signs of acute pericarditis were observed in 19 cases. It is noteworthy that only in these patients did pleurisy, with or without effusion, and pneumonia develop. In 5 cases, signs of pericardial effusion were elicited.

The spleen was slightly enlarged in 5 cases.

Skin lesions, when present, were usually those of erythema multiforme, but in some cases small ecchymotic areas were noted at the site of the affected joints, spreading to involve the other parts of the extremities. Subcutaneous nodules were not found in any patient of this series.

Rapid loss of weight, amounting to as much as 16 to 20 pounds, was almost invariably noted during the acute stage of the illness.

Electrocardiographic changes were observed in 63 per cent of the patients, often after only a few days of illness. These occurred with increasing frequency when serial electrocardiographic studies were made. The most frequent abnormality was prolongation of the auriculoventricular conduction time, the longest PR interval being 0.62 second. In a number of cases, although the PR intervals were within the range of normal (0.12 to 0.21 second), repeated electrocardiograms showed variations in excess of 0.02 second. These variations were inter-

preted as being significant of first-degree auriculoventricular block. They emphasize the importance of frequent electrocardiographic tracings in the same patient. All degrees of auriculoventricular block were observed, and occasionally that of the indeterminate type was seen. At times the QRS complexes were inverted and notched in Lead CF₄, and the ST segments were either elevated or depressed beyond normal in one or more leads. The T waves often became tiny, diphasic or inverted in one or more leads, especially in Lead CF₄. In the patients with physical signs of pericarditis, the T waves usually became inverted in the limb leads but the ST changes were slight. Premature systoles were frequently noted. Of the other arrhythmias, paroxysmal auricular tachycardia, auricular fibrillation and auricular flutter occurred in isolated cases. The occurrence of interference dissociation in 18 cases was of clinical interest, although of no pathological significance. This abnormality, ascribed to hyperirritability of the auriculoventricular node, occurred only during the acute stage of illness. The electrocardiographic changes were transient in almost all the cases, usually returning to normal within seven to twenty-one days but occasionally persisting for as long as five months. When right or left ventricular preponderance developed, it generally remained during the entire period of observation. It is noteworthy that the electrocardiographic abnormalities were more frequent and also more marked in the patients admitted to the hospital during the peak of the epidemic periods.

An increased sedimentation rate has generally been regarded as a constant finding in acute rheumatic fever. In the vast majority of cases our findings were in agreement with this observation, but in a small number of patients with mild joint involvement and electrocardiographic evidence of first-degree auriculoventricular block the sedimentation rate was repeatedly normal. Thus, the deduction may be drawn that a normal rate does not preclude the existence of active rheumatic fever.

The white-cell count usually showed a leukocytosis, ranging between 10,500 and 16,000. In the minority of patients, a mild hypochromic anemia was found. Albuminuria, pyuria and microscopic hematuria were frequently present on admission, they generally disappeared within several days.

COURSE

The course was variable, depending on the tenacity of the rheumatic infection. The great majority of patients recovered after a single bout of fever and ran a relatively benign course. In the others, either the acute stage was followed by a long period of low-grade activity or the remission was punctuated by a recrudescence of symptoms, usually subsequent to a hemolytic streptococcus infection of the upper respiratory tract. It is well recognized that the danger of disabling heart disease

lies principally in the cases that pursue one or the other of the latter courses. In this series, the paranasal sinuses were found to be the usual focus of persistent infection, the eradication of which shortened the course of the disease.

Only 5 fatalities occurred. In 3 of these cases, there was evidence of terminal uremia and autopsy revealed subacute glomerulonephritis. In the other 2, death resulted from congestive heart failure.

DIAGNOSIS

In the typical case, when acute migratory polyarthritis is found in association with acute carditis, electrocardiographic abnormalities, leukocytosis and an increased sedimentation rate, the diagnosis of rheumatic fever may be made without equivocation. As indicated by the foregoing description, however, many patients do not present this combination of findings, and in these the diagnosis is likely to be difficult and the clinical picture confusing. Indeed, the manifestations of rheumatic fever may be so similar as to simulate those of many diseases. Hence, in patients with fever accompanied by arthralgia, muscular pains and stiffness, precordial pain and dyspnea, acute abdominal symptoms or acute pyelonephritis and in whom the diagnosis is in doubt, as well as in those with pyrexia of unknown origin, the possibility of rheumatic fever must receive consideration. It is unfortunate that there exists today no specific diagnostic test for rheumatic fever, and until such a test is forthcoming, careful and prolonged clinical observation is necessary in these cases. Errors in diagnosis may be inescapable, especially in patients with arthralgia and low-grade fever, representing the milder forms of rheumatic fever, a fact that has also been emphasized by Jones.¹ A history of antecedent rheumatic fever or chorea should be regarded as highly significant, whereas a familial history of rheumatic fever may be of some help and should receive consideration. Electrocardiographic changes, particularly prolongation of the conduction time, should be considered as strong evidence in support of rheumatic fever, but it must be recognized that they are not diagnostic and that at times other infections produce similar changes (Rosenberg²). The development of systolic murmurs per se cannot be regarded as of diagnostic value, inasmuch as they may appear during the course of any acute infectious disease and are usually produced by relative dilatation of the cardiac orifice, but the appearance of diastolic murmurs at the left third interspace near the sternum or at the aortic area, mid-diastolic murmurs at the mitral area — in the absence of aortic regurgitation — or signs of acute pericarditis may be considered as confirmatory. Determination of the antistreptolysin titer may be helpful, but only as an indication of a recent hemolytic streptococcus infection. In doubtful cases the absence of anti-

streptolysins tends to negate the diagnosis of rheumatic fever.

Of the many diseases that may resemble rheumatic fever, acute rheumatoid arthritis is the most frequent one. It may be differentiated by the persistent periarticular swelling of the small joints, resulting in deformities, a predilection for the proximal interphalangeal joints of the fingers and the usual freedom from cardiac involvement. It should be pointed out, however, that the relation between these diseases is still controversial and that they may coexist. Gonococcal arthritis may confuse the diagnosis, but the recovery of the specific organism from the joint fluid is conclusive evidence. The finding of gonococci in the genitourinary tract in a patient with a recent history of gonorrhea may also be regarded as presumptive evidence of gonococcal arthritis. On the other hand, a positive complement fixation test has not by itself been found to be a reliable diagnostic aid. Septic arthritis and arthritis secondary to other acute infectious diseases may be suspected from the antecedent history of infection or from the concomitant disease. Undulant fever is generally associated with arthritis and may be identified by the finding of a high titer of specific agglutinins in the blood serum, by intradermal skin tests or by positive blood cultures. Serum sickness may also produce febrile reactions with acute polyarticular manifestations. On the other hand, a history of serum administration seven to ten days previously, the presence of urticaria and the absence of redness of the joints serve to differentiate the disease. The premeningeal stage of acute meningococcemia, when accompanied by acute arthritis, may resemble acute rheumatic fever. It may be distinguished by the history, the presence of a generalized petechial eruption and corroboratory bacteriologic studies. Acute gout at times masquerades as rheumatic fever. In these cases, the hyperuricemia, roentgenographic findings in the bones and a prompt response to colchicin leave little doubt as to the correct diagnosis. Other diseases, such as disseminated lupus erythematosus and periarteritis nodosa, may require differentiation, but they are far less frequent than those just discussed.

TREATMENT

The treatment of these patients consisted of complete bed rest and the giving of 2500 to 3000 cc of fluids daily, 8 to 10 gm of sodium salicylate and 6 to 8 gm of sodium bicarbonate daily, 0.033 gm of codeine sulfate when indicated for severe joint pain and a high-calorie, high-vitamin diet. Salicylism occurred with extreme infrequency with the lower dosage. Patients with gastric distress received 4 gm of sodium salicylate in 120 cc of starch solution as a retention enema four times daily. In some cases 0.67 gm of amidopyrine or 1 gm of acetylsalicylic acid, administered four times daily instead of enemas, was well tolerated. When amidopyrine was

administered, the white-cell count was followed closely

These dosages were usually maintained for two weeks. When the patient became asymptomatic, and the sedimentation rate normal, the dosage was reduced by a half and continued for another month. In the event of a relapse when the influence of the drug had worn off, whether with or without fever, salicylates and bed rest were resumed and were continued until the sedimentation rate had remained normal for two or more weeks. The efficacy of salicylates in the suppression of such recurrences was clearly demonstrated in these cases.

All patients were kept at complete bed rest for a minimum period of six weeks, and it was required that the temperature, pulse, sedimentation rate and white-cell count were normal before the patient was permitted out of bed. Depending on the degree of cardiac damage, bed rest was generally maintained for four to six weeks after the electrocardiogram had become normal. The period spent out of bed was slowly increased and physical activities were graduated, special attention being devoted to the pulse.

Under such management, the joint involvement, fever and tachycardia usually subsided within three or four days, and the sedimentation rate generally returned to normal in two or three weeks. In the acutely ill patients, improvement was more protracted, seven to fourteen days elapsing before the joints, temperature and pulse became normal. With continued improvement the heart sounds returned to normal, and gallop rhythm, when present, disappeared. Systolic murmurs frequently diminished in intensity or became confined to the mitral area, in many cases they disappeared, even though formerly loud and widely transmitted.

Coburn's³ therapeutic technic was employed in some of the acutely ill patients and in those who were refractory or showed gastric intolerance to oral therapy. Doses of 1000 to 2000 cc of 1 per cent sodium salicylate in isotonic saline solution were administered daily by slow intravenous drip, a blood-salicylate level of at least 350 microgm per cubic centimeter being maintained. This regime was continued until the patient was asymptomatic and afebrile, and until the sedimentation rate had dropped by about 20 per cent. When these criteria were fulfilled, intravenous treatment was replaced by oral therapy. Relief of symptoms was often effected more rapidly by this method than by others, and patients refractory to oral therapy were at times benefited. Nausea, vomiting, tinnitus and deafness, however, occurred quite often, and in 2 cases marked cerebral symptoms were noted in the form of delirium and stupor, which disappeared when salicylates were discontinued.

Sulfadiazine was given to 5 patients according to the plan generally followed in the treatment of pneumonia. No beneficial effects were noted, on

the contrary, the polyarthritis became intensified and the fever remained high and continuous. No conclusion could be drawn concerning any untoward cardiac effects. In all cases, the symptoms subsided promptly when salicylates were substituted.

Penicillin was administered to 5 patients in doses of 20,000 units intramuscularly every three hours to a total of 1,000,000 units. Electrocardiograms, white-cell counts and sedimentation rates were taken daily, and the patients were kept under close observation. No beneficial effects could be attributed to this form of therapy, nor were any ill effects noted. These conclusions are in agreement with those reported by Watson, Rothbard and Swift⁴ and by Foster, McEachern et al.⁵ A prompt symptomatic response was obtained with salicylates in these patients.

Digitalis was employed only in patients with congestive heart failure or a persistent tachycardia of 125 or more and in those with auricular fibrillation and flutter. Aspiration of the pericardial sac was not found necessary in any patient with pericardial effusion. In 2 patients with extensive pleural effusion, thoracentesis was required for the relief of marked respiratory embarrassment.

Residual stiffness and mild aching in the joints were noted in some patients after all evidence of active rheumatic infection had disappeared, these were especially prominent during cold or damp weather. Diathermy and massage were beneficial in many of these cases. The mild aching in the feet and ankles observed on walking was improved by whirlpool baths.

Finally, although the maintenance of a high nutritional state is important, it is agreed that to attain the ultimate goal in the recovery of patients with rheumatic fever all efforts must be directed to the prevention of recurrences. Recent studies conducted by Thomas and her co-workers,⁷ Coburn⁸ and Holbrook⁹ suggest that the incidence of recurrences may be significantly reduced by the elimination of hemolytic streptococcus infections through the prophylactic use of sulfonamide drugs. Additional well controlled studies will be necessary, however, to settle this matter beyond doubt. Furthermore, in drawing conclusions from such studies one must not lose sight of the probability that resistant strains of hemolytic streptococci may be encountered in some localities and in different epidemics. In such cases, sulfonamides are ineffective.

SUMMARY

A composite picture of the clinical manifestations of acute rheumatic fever as observed in a series of 1000 patients in the naval service is presented.

The importance of recognizing rheumatic fever in adults is emphasized, and the difficulties in its early diagnosis are discussed.

The therapeutic effects of salicylates, sulfadiazine and penicillin are recorded.

AINHUM*

MAURAY TYE, M.D.†

BOSTON

AINHUM, or spontaneous dactylolysis, which occurs predominately in male Negroes, has been described as a distinct disease by some authors and as a symptom by others. At the digitoplantar fold there appears a constricting ring of fibrous tissue, which deepens and finally strangulates the underlying structures, producing spontaneous amputation.

Weinstein¹ gives Messum² credit for the original description of the condition in 1821, but most authors give it to Clark,³ who in 1860 described a lesion considered as a sequela to yaws in natives of the Gold Coast. The name of the disease and the first adequate description of it were published by da Silva Lima⁴ in 1867, and the first pathological study was made by Wucherer.⁵ Hornaday⁶ in 1881 reported the first case in the United States, which occurred in North Carolina in a ten-year-old Negress.

According to Matas,⁷ "ainhum" is derived from the Brazilian Negro *patois*, meaning "fissure." Da Silva Lima⁴ traced it to the Nagos word meaning "sawing off." In one of the African dialects "ainhum" signifies "compression."

The greatest number of cases have been reported among the Negroes of the west coast of Africa, the West Indies and South America. Isolated cases have been reported from Europe, Russia, Istanbul and India, and about 45 cases have been seen in the United States—most of them in the southern states, a few in New York and the rest in localities scattered over the country. The case reported below is the first in New England.

A 77-year-old, unemployed Negro, a native of Barbados, West Indies, who had lived in and about Boston for the last 50 years, entered the hospital because of constriction and discoloration of the left 5th toe. He had been aware of this condition for 6 to 8 months before admission, but it had caused no symptomatic difficulty except a progressive gradual narrowing at the base. There was no history of trauma, no unusual footwear had been worn, and there had been no infection of the feet. The patient denied having had any venereal disease, by name and symptoms, diabetes or intermittent

claudication. No other members of the family had had a similar condition. The diet was adequate.

Physical examination on admission revealed a well developed, well nourished, well preserved Negro, able to walk without pain or discomfort. The temperature was 98.8°F., the pulse 90, the respirations 20, and the blood pressure 170/100. The patient was mentally alert and intelligent. The skin was not discolored and was of good texture, and

FIGURE 1

there were no keloid changes. The left 5th toe was purplish, warm, supple and slightly larger than the corresponding right toe. It was fissured at the digital plantar fold. Its distal portion, which was adherent at the lateral margin of the foot, was held only by a fibrous band 0.5 cm. in diameter. There was no discoloration of any of the other toes. The pulsation of the dorsalis pedis artery was faintly palpable. Sensory and vibratory sensations were physiologic, and there were no abnormal reflexes.

The hemoglobin was 90 per cent and the white-cell count 5500, with 60 per cent neutrophils, 22 per cent lymphocytes, 8 per cent monocytes and 2 per cent eosinophils. The red cells appeared normal. The serum nonprotein nitrogen was 35 mg.

*From the Department of Dermatology and Syphilology, Boston City Hospital.

†Graduate assistant in dermatology and syphilology, Boston City Hospital, teaching fellow in dermatology and syphilology, Boston University School of Medicine.

per 100 cc., and the fasting blood sugar 95 mg. A blood Hinton test was negative. The urine was yellow and had a specific gravity of 1.020. It contained no albumin, sugar or bile. The sediment showed 1 or 2 white cells per high-power field, but no red cells or casts.

X-ray examination showed absence of the middle phalanx of the little toe and destruction of the proximal portion of the terminal phalanx, with marked osteoporosis (Fig 1). The distal and middle portions of the proximal phalanx of the 5th toe were absent, only the base and a small, markedly narrowed fragment of the shaft remaining. There was atrophy of the bones of the foot, most marked in the toes.

There was a sharp constriction in the soft tissues of the 5th toe, which was almost completely separated from the foot. In a few days the toe became cold, dry, shriveled, firm and black and hung loosely, held only by a narrow tag of sclerotic tissue (Fig 2).

The fibrous band was cut with scissors and the toe was painlessly removed. There was neither bleeding nor ulceration, and only a small fibrous tab of tissue remained. There was no discoloration of the skin proximal to the site of amputation. The patient remained completely asymptomatic and was discharged. Follow-up in the Out-Patient Department 2 months later showed no change in the condition of the foot.

Microscopical examination of the epidermis showed the stratum corneum to be thickened, most markedly so near the point of amputation, the stratum lucidum was not identified but the stratum granulosum was clearly defined. Nuclei were preserved in this and deeper layers. Pigment remained in the basal cell layer. The derma was composed of dense connective tissue.

FIGURE 2

tive tissue. Within the derma and the dermal papillae, as well as within the deeper subcutaneous tissues, there were large numbers of dilated, thin-walled vessels, which were largest and most numerous just distal to the point of amputation. There was a decrease in the amount of remaining bone, which consisted of irregular trabeculae. Fat filled the trabecular spaces. No bone was found just distal to the point of amputation, where collagenous connective tissue had replaced the bone. Strands of collagenous connective tissue surrounded the centrally placed bony trabeculae. In longitudinal sections nearest the point of amputation, the tissue was composed of skin and a central core of collagenous connective tissue.

Many theories have been advanced to explain this condition. Da Silva Lima⁴ has suggested that injuries to the toes by sharp grasses produce contracting cicatrices, but the disease has been reported in Negroes who have worn shoes, and it does not occur equally in all races accustomed to going barefoot. Eyles⁵ believed that the digitoplantar fold was a favorable site for irritation from foreign

matter, hypertrophy of the epidermis and pressure on vasomotor nerves, resulting in the trophic phenomena. A theory that the condition is a result of leprosy, advanced by Pacha,⁹ has been discarded as a result of histologic studies and bacteriologic examinations that have never shown the leprosy bacillus. Similarly, the belief that syphilis is⁷ a causal factor has been discarded. Scheube,¹⁰ Weinstein¹ and Abbe¹¹ advanced the concept of ainhum as a trophoneurosis, but no nerve lesions have been found. Some writers, notably Wellman,¹² have considered infection by chiggers an etiologic factor. Davies and Hewer¹³ suggested that chronic epidermophytosis might produce an excess of scar tissue and thus constriction of the toe. Constrictions resembling those of ainhum have been described in scleroderma¹⁴ and in keratoderma.^{15, 16} Bloom and Newman¹⁷ considered the pathologic process as a mechanical one produced by a fibrotic constriction induced by some previous mechanical or infectious injury.

A few cases of this disease have been reported in white persons, notably by Arby, Debrum, Hyde-Montgomery and Castellani, according to Bloom and Newman.¹⁷ Weinstein¹ and Doyle¹⁸ believed that there was some familial tendency toward the disease. Ainhum rarely attacks those who have not reached adolescence, the greatest incidence being in persons between twenty and forty years of age. Weinstein,¹ however, stated that following the literature he was struck by the comparative old age of some of the patients. About 10 per cent of the cases in the United States have developed in persons between sixty and eighty years old.

Ainhum usually affects one or both of the fifth toes at the first interphalangeal articulation, either simultaneously or successively—rarely the fourth toe and less frequently the second phalanx. It generally begins as a circular depression at the internal, inferior aspect of the web of the little toe and gradually progresses, surrounding the toe, with the outer margin the last part to be involved. In most cases there is no pain at the commencement of the disease, but late in the course this symptom may be prominent. The portion of the toe distal to the locus of constriction frequently swells to a large globular segment with an intact nail. Later the phalangeal bone at the level of the constriction divides, the skin color changes, and there is loss of voluntary control. All this requires from six months to several years to develop, the course in most cases covering two to five years.

Spinzig¹⁹ summarizes the pathological findings as follows:

A hypertrophy of the epidermis occurs in the vicinity of the constriction. The papillae are elongated and enlarged. The arteries are thickened and engorged with blood cells, while the veins are usually empty. There is some perivascular infiltration of round cells. In the corium are usually arranged bundles of connective tissue with fat and some round-cell tissue and edema. The sweat

glands show signs of atrophy. A rarefying osteitis involves the bone with areas of destruction. Those areas are filled with connective tissue and fat and the bone is gradually replaced with fibrous tissue.

X-ray examination demonstrates the soft-tissue constrictions, there is complete or partial bony absorption of the distal phalanx and the proximal phalanx, although still present usually shows some absorption of the distal portion.

Many entities are to be considered in the differential diagnosis, but most of these are readily excluded. Leprosy mutilans is ruled out, according to Acton,²⁰ by the presence of anesthesia of the part, as a result of which trauma and burns produce ulcers that extend to the joints. Furthermore, all the toes are usually involved in this disease.

Morvan's disease and syringomyelia are excluded by the fact that in these diseases sensory disturbances of cold, heat and pain are lost, together with muscular power. The arms are generally affected as well.

Another condition to be considered is scleroderma. In this disease the skin is indurated, multiple digits are affected, and constitutional symptoms are frequent. The incidence is highest among females. The indurated, localized bandlike counterworkings may, however, offer difficulty in differentiation.

Congenital constrictions of the digits are usually not limited to the toes and are generally present from birth.

Castellani²¹ believed amputation to be the best method of treatment. Da Silva Lima⁴ thought that if the constriction was cut perpendicularly early it might be cured, but according to Gerwig and Warner,²² splitting of the fibrous band is often followed by recurrence. Irgang and Alexander²³ relieved the pain in 1 case with sodium iodide. Others have tried calcium, thyroid and parathyroid, without success. Lumbar sympathectomy²⁴ and plexus treat-

ment, with alternation of positive and negative pressure, have failed to influence the disease.

SUMMARY

The first case from New England of ainhum, or spontaneous dactylolysis, is reported. The results of pathological study and the roentgenologic findings are reported, and the literature is reviewed.

SYMPOSIUM ON MEDICAL SOCIOLOGY

FOREIGN PROGRAMS OF MEDICAL CARE AND THEIR LESSONS*

FRANZ GOLDMANN, M D †

IT IS a simple matter to state that complete medical care of the finest type is wanted for the greatest possible number of people at the least possible expense, but it is a Herculean task to translate such a need into a practical and workable plan. In the course of some sixty years, various types of medical-care programs have been tried out in a score of foreign countries. There is a wealth of experience regarding the relative merits of the basic methods of organizing and administering programs for the care of the sick. Some of the fundamental principles introduced late in the nineteenth century have proved to be sound and capable of wide application, others have been found to be inadequate, although they have not fallen into complete oblivion. In concern for tomorrow one must not forget the lessons of yesterday — and there are many lessons to be learned from both the achievements and the shortcomings of policies for organizing medical care.

Instead of describing details of some of the programs adopted abroad, I shall focus attention on the common elements in the vast number of developments that have taken place when enthusiasm crystallized into programs, and on the guiding principles of organization and administration that have emerged in the process of a piecemeal, and often haphazard, growth. I shall briefly discuss the methods of organizing professional services and facilities for medical care, the methods of organizing payment for medical care, the administrative organization of medical-care programs and the social philosophy underlying foreign developments.

* * *

In organizing professional services, the prevailing policy has been, and still is, to preserve the old-established principles of practicing medicine — those of private practice, individual practice and free choice of a physician. In a score of countries these three principles have been incorporated in social-insurance laws as well as in public-assistance statutes. They have been observed regardless of the method chosen for organization of payment for professional services. As experience accumulated, the wisdom of continuing the old policy was increasingly questioned. There was little inclination

to discard the principle of private practice, but there have been some exceptions to the rule that deserve mention.

Russia, in line with her political ideology, has chosen the system of salaried medical service under government control. Private practice, although not forbidden, plays no role worth speaking of. Some hundred rural "municipalities" in certain Canadian provinces, notably Saskatchewan and Manitoba, have adopted the so-called "municipal doctor scheme," under which one or several salaried physicians are employed by the community to render service to all residents. A few months ago the Saskatchewan Government announced plans for the extension of this system throughout the province. Similar programs have been introduced in some rural areas of Australia, in particular in the Northern Territory, Queensland and Tasmania.

Whereas the principle of private practice has been maintained in the vast majority of all foreign countries, the system of individual practice has been increasingly criticized. There has been growing realization of the need to adjust medical practice to the rapid scientific progress and the profound socioeconomic changes that have taken place since the nineteenth century — the good old days when there was justification for the saying, "God cures the sick and the doctor takes the fees." It is now generally recognized that the attainment of quality, efficiency and economy of service is of prime importance in planning for the future. Two specific problems stand out as particularly pressing: the co-ordination of the work of the general practitioner and the specialist, since the latter should complement rather than supplant the former, and the integration of so-called "preventive" services and "curative" services, since these cannot be separated without injuring both.

To improve the situation, the introduction of the group practice of medicine has been increasingly recommended, primarily in the last two decades. The term "group practice" denotes a system of co-operative practice of medicine by physicians for the purpose of pooling experience and skill, facilities and equipment, technical and other auxiliary personnel and operating expenses, if not also earnings. Group practice is first of all a method to promote the scientific co-operation of the medical and allied professions for the welfare of the sick. Although it has no direct relation to the method of paying for medical care, the system gains in value if the economies it affords are passed on to the patient.

*This is the fifth of a series of nine lectures on medical sociology given weekly at Harvard Medical School during January, February and March 1945. They were sponsored by the Department of Preventive Medicine, and were primarily intended for third-year students. These articles will temporarily replace the reports "Medical Progress."

†Some of the statements in this paper are taken from the author's book *Public Medical Care* (New York: Columbia University Press, 1945). The publisher's permission to use this material is gratefully acknowledged.

†Associate clinical professor of public health, Yale University School of Medicine, New Haven, Connecticut.

Well organized group practice conducted from a properly staffed and well equipped center, such as a clinic or a hospital, greatly benefits the patient, the health professions and the community. It provides for better and more service in a convenient way, serves to attain consistency and continuity of treatment and reduces the costs of medical care for both patients and physicians. It gives the physicians and related groups opportunities for professional improvement through consultation, research and postgraduate study, a satisfactory income, greater freedom from night calls, Sunday work and evening hours, and paid vacations. It fills a gap in the community-health program by making good medical care, both preventive and curative, available at reasonable costs.

On a limited scale, group practice has been developed in a few countries, such as Chile, France, Germany and Peru, in all instances in connection with social-insurance programs. It is interesting that in Germany group practice was abolished by the Hitler régime in line with its political ideology. Even the limited experience gained abroad clearly shows that group practice compares favorably with individual practice, since better and more service can be given at lower costs, and this tallies with the experience acquired by group clinics in this country. Significantly, recent legislative proposals in Canada and Great Britain recognize group practice and want to try it out on a larger scale. Going a step farther, the National Health and Medical Research Council of Australia has proposed the general introduction of group practice, along with the establishment of a system of so-called "consultation centers" throughout the country.

The lesson that can be learned from the development abroad is as follows. Originally, little attention was paid to the organization of professional services, and major emphasis was placed on the development of payment plans based on the insurance principle. Belatedly, it was recognized that failure to adjust the organization of professional services to modern requirements endangered the effective and economical operation of any organized program of medical care.

The organization of hospitals and clinics abroad has advanced remarkably far. The major problem was to decide on the responsibility for construction and equipment and the improvement of all the medical-care facilities necessary to meet individual requirements as well as to satisfy the community's need for adequate, humane and economical service. There are two schools of thought abroad. One group believes that all medical-care facilities ought to be established at public expense, exactly as is done with schools, highways, utilities, recreational facilities and similar services essential for the welfare of the individual as well as that of the social organism. Opponents of this policy — and there are many — insist that public policy should not deny

scope and opportunity in one of the most appealing fields to the expression and practice of freely accorded individual benevolence. They do not, however, question the obligation of government to provide for certain types of facilities.

Actually one finds four distinct policies abroad. In Russia, all hospitals and clinics are owned and operated by the state. In a considerable number of countries, the great majority of all hospitals and clinics are built by local, state or national governments. Nongovernmental activities in this field are not only permitted but closely co-ordinated with those of public agencies. Nongovernmental facilities, however, must meet strict requirements as to quality, have a license to operate, and accept supervision by public authorities. Another group of countries believe that government's responsibility should be confined to provision of selected types of facilities, such as isolation, mental and tuberculosis hospitals and certain types of preventive clinics, voluntary organizations being encouraged to provide for general and allied hospitals as well as clinics of various types. Still another group of countries, including some in South America, have encouraged the construction of hospitals by social-insurance organizations.

A few examples will serve to illustrate some of these policies. In Sweden and Great Britain, all isolation hospitals are government-owned. Great Britain has about 1000 public isolation hospitals with some 40,000 beds. In Sweden, Great Britain and New Zealand, nearly all beds for mental patients are in governmental institutions, as compared with 97 per cent of such beds in this country. In Great Britain, about three fourths of all the tuberculosis beds are in public institutions, as compared with more than four fifths in the United States. In the Scandinavian countries, Austria and Germany, general hospitals are mainly public, and nongovernmental hospitals are utilized and paid by public and semipublic agencies for services rendered to designated groups. A predominantly voluntary system of general hospitals is found in France and Great Britain, although lately voluntary facilities have been losing ground. Clinics under public auspices constitute the vast majority of such facilities in a large number of countries, including the Scandinavian countries, Great Britain, Ireland, Austria, Germany and several South American countries. In Great Britain, more than 2000 school clinics and about 2500 maternal and child-health centers, or four fifths of all these centers, are maintained by public authorities.

In a score of countries, the marked change in social philosophy, expressed in the shift from private to public responsibility for the establishment of all necessary medical-care facilities, has raised intricate problems. Some groups and individuals argue that there is no longer any justification for the voluntary hospital system and hold that nongovernmental

ospitals should be abolished in favor of a system of public hospitals. Others believe that voluntary hospitals should not be prevented from operating, provided that they meet standards of adequacy and are functionally co-ordinated with governmental hospitals. The clinic problem too is being hotly debated. In the course of a haphazard development numerous types of clinics have come into existence, some organized for preventive service only, some emphasizing treatment service, some serving exclusively the needy and some admitting selected groups of self-supporting patients. The wisdom of continuing such artificial distinctions is increasingly questioned, and a new approach to the clinic problem is urged. Instead of a variety of clinics with different functions and serving different socioeconomic groups, there should be established medical centers or health centers to provide both preventive health services and care in sickness for all residents of the community. These centers should serve as the headquarters of physicians and related groups in private practice as well as of personnel employed by public and private agencies. Pertinent recommendations to this effect appear in several legislative proposals recently advanced in foreign countries.

* * *

There are two basic methods of organizing payment for professional and institutional services: taxation and insurance. When the method of taxation is used, revenues are raised primarily through taxes on property and income and to some extent through excise taxes such as sales, liquor and tobacco taxes. When the method of insurance is employed, the funds are raised in a quite different way. Insurance against the economic hazards of sickness, injury and maternity is a method of pooling risks and resources to budget and pay the cost of medical care or to compensate for loss of earnings due to disability, or to fulfill both these functions. The principle of insurance implies that many persons must band together under a single plan to spread their risks and must make small regular prepayments into a common fund to pool their resources. Thus, health insurance is organized self-help to remove or reduce the financial burden that may arise from sickness, injury or maternity. People can budget and pay for services and cash benefits when they are well and earning; they can obtain service to prevent illness and incapacity for work and receive medical care and compensation for disability when they are sick and disabled.

Both methods of financing medical care are in wide use abroad, although there are significant differences in the extent to which they are employed. Russia, in 1937, abandoned the method of financing medical care through insurance and since that time has been supporting her medical-care program out of general tax revenues. Only a few services, such as convalescent care and treatment

in health resorts, are still financed through social insurance. In many other foreign countries the method of taxation is employed on a more limited scale. The policies differ greatly from country to country owing to wide variations in needs and available resources as well as in social philosophy. A few examples will serve to illustrate this point.

In Sweden, tax funds defray all but about 15 per cent of the expenditures for operating communicable-disease hospitals. This is an outstanding example of a policy designed to support the control of communicable disease by providing for most liberal hospitalization at public expense without regard to the economic conditions of the patient. In Ireland, there are a large number of public treatment clinics, and the policy responsible for them dates back to the early nineteenth century. These centers provide for home care as well as clinic care and serve all persons in need; the interpretation of such need is quite liberal. In a large number of countries, such as Austria, Germany, Great Britain and the Scandinavian countries, the tuberculosis-control or venereal-disease-control program, or both of them, are supported primarily out of tax funds. The eligibility standards for medical care at public expense are such as to enable the large majority of the people to receive any service they need. In some countries, there developed a multitude of special tax-supported programs with different standards of eligibility and service, all operating separately. That such a policy inevitably has patchwork results is now fully recognized. An attempt has been made in recent proposals to remedy the situation by integrating special programs into over-all programs. Nearly all foreign countries use tax funds to pay for the medical care of selected groups of persons, primarily war veterans and the recipients of public assistance. Extension of tax-supported medical care to self-supporting persons is widely regarded as unsound policy. The system of public medical care for those in need necessarily involves application of the person involved and determination of his eligibility by a so-called "means test." Under this system, the applicant and his family must have exhausted most, if not all, of their own resources before they can be accepted for a service that in the final analysis is a last resort. Charity, well intended as it is, is not what the common man wants. Restriction of service to persons in need jeopardizes preventive action. It comes too late to prevent complications, serious illness and chronic stages of sickness, and too late to permit the most economical use of the taxpayers' money. It is the considered opinion of nearly all experts abroad that the public-assistance approach to the organization of medical care is highly undesirable, and that it should be employed as little as possible.

Recognizing the inadequacy of the public-assistance approach to health security, a steadily

persons able to make regular prepayments, and it is hard to establish and to administer in thinly settled areas. For these reasons, all the countries having compulsory sickness-insurance programs also maintain complementary programs of medical care financed out of general tax revenues

* * *

The administrative organization of foreign programs of medical care is distinguished by a well known feature: multiplicity of agencies. A few significant trends may be discussed briefly. Usually, the national governments have accepted responsibility for nationwide policy-making and, to varying extents, for supervision of standards and financial participation. They share responsibility with governments at other levels. Small administrative units have been more and more discarded, since they have proved inadequate for the purpose of financing and administering medical-care programs. Instead, large units, such as counties, districts and regions, are vested with financial and administrative powers and functions. Administration of compulsory sickness-insurance schemes is generally separated from the administration of all other health services and entrusted to special statutory bodies. Thus, a state within the state has been created. The result has been overlapping, friction and waste of administrative effort on the one hand and neglect of some fields of health service on the other. The old principle of lay control of health services has been more and more abandoned in favor of professional supervision of professional matters — the physician, the dentist, the pharmacist and others each being responsible in his own field. These professional persons have authority to decide on the technical and professional aspects of medical care under social-insurance as well as other programs

* * *

Planning for adequate medical care is more than a method of organizing the application of scientific

knowledge and technical skill. It is the expression of a social philosophy. It is effective only in so far as it is sustained by a conviction of principle. The philosophy underlying modern health policy abroad rests on two cornerstones — society's need of the fit and productive person and the individual's right to health.

In essence, these ideas were expressed as far back as the end of the eighteenth century, when France issued the Declaration of the Rights of Man, and again in recent national constitutions, such as those of the Weimar Republic and the Union of Soviet Socialist Republics. New concepts have emerged, holding that the health of the people is a public concern, that sickness is more than a private misfortune, and that medical care in its widest sense is an essential human right, to be guaranteed and safeguarded in any program for personal and social security. Protection of the right to health is a fundamental function of any society aspiring to a genuine and rational economy of human resources and values. Government of the people, by the people and for the people has an obligation in this field. Nobody has expressed this better than Abraham Lincoln: "The legitimate object of government is to do for a community of people whatever they need to have done but cannot do at all, or cannot do so well for themselves, in their separate and individual capacities."

CASE 32051

PRESENTATION OF CASE

A fifty-six-year-old janitor entered the hospital complaining of weakness.

Seven weeks before admission he consulted a physician because he did not feel well. He was told that he was anemic and was given liver injections. Ten days before admission he felt dizzy and faint, and at about the same time his skin became somewhat yellow. The urine was not dark, nor were the stools clay colored. At no time had the patient complained of nausea, vomiting, diarrhea or constipation. He had lost 25 pounds in weight in six months, despite a good appetite.

Physical examination revealed a pale, thin man in no acute discomfort. The skin and scleras were slightly yellow. The heart and lungs were normal. The liver edge was palpated 7 cm below the right costal margin, it was smooth and slightly tender. The prostate was smooth, firm and symmetrically enlarged.

The temperature was 99°F, the pulse 80, and the respirations 20. The blood pressure was 100 systolic, 60 diastolic.

The red-cell count was 2,100,000, with 49 gm of hemoglobin. The white-cell count was 12,000, with 82 per cent neutrophils. Many macrocytes were present, but the red cells were generally normochromic. The mean corpuscular volume was 85 cu microns, the mean corpuscular hemoglobin 20.8 micromicrogm, and the mean corpuscular hemoglobin concentration 24.4 per cent. The urine was normal. The nonprotein nitrogen was 19 mg per 100 cc. The total serum protein was 5.9 gm per 100 cc, with 3.0 gm of albumin and 2.9 gm of globulin. The serum calcium was 7.7 mg per 100 cc, the phosphorus 1.5 mg, and the alkaline phosphatase 27.5 Bodansky units. The serum bilirubin was 0.9 mg per 100 cc direct, and 1.3 mg indirect. The serum cholesterol was 156 mg per 100 cc. A cephalin flocculation test was ++ in twenty-four hours, and ++++ in forty-eight hours. The prothrombin time was 21 seconds (normal, 15 to 17 seconds). A bromsulfalein test showed 20 per cent retention. The gastric juice contained free hydrochloric acid. The stools varied

from yellow to gray, and five out of seventeen specimens were guaiac positive.

An x-ray film of the chest was essentially negative. A gastrointestinal series revealed a normal esophagus. A small portion of the fundus of the stomach protruded through a hiatus hernia but was easily reduced. The second part of the duodenum was constantly rigid in its upper portion, with an irregular filling defect and loss of mucosal pattern along its medial wall, which contained a small central ulceration (Figs 1 and 2). A questionable defect was present in the lower portion of the ascending part of the duodenal loop, where the mucosal

FIGURE 1 Roentgenogram Showing Narrowed and Rigid Area of Second Portion of Duodenum

pattern was preserved. A barium enema was negative.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR MARSHALL K BARTLETT May we see the x-ray films?

DR MILFORD D SCHULZ The films show a normal chest and a normal colon. In the second portion of the duodenum, however, just below the duodenal bulb and along the lesser curvature, is an area of narrowing that is quite smooth and seems to be constant. It is present in a number of films. In the central portion of this defect on two films is a

persons able to make regular prepayments, and it is hard to establish and to administer in thinly settled areas. For these reasons, all the countries having compulsory sickness-insurance programs also maintain complementary programs of medical care financed out of general tax revenues

A fifty-six-year-old janitor entered the hospital complaining of weakness.

Seven weeks before admission he consulted a physician because he did not feel well. He was told that he was anemic and was given liver injections. Ten days before admission he felt dizzy and faint, and at about the same time his skin became somewhat yellow. The urine was not dark, nor were the stools clay colored. At no time had the patient complained of nausea, vomiting, diarrhea or constipation. He had lost 25 pounds in weight in six months, despite a good appetite.

Physical examination revealed a pale, thin man in no acute discomfort. The skin and scleras were slightly yellow. The heart and lungs were normal. The liver edge was palpated 7 cm. below the right costal margin, it was smooth and slightly tender. The prostate was smooth, firm and symmetrically enlarged.

The temperature was 99°F, the pulse 80, and the respirations 20. The blood pressure was 100 systolic, 60 diastolic.

The red-cell count was 2,100,000, with 4.9 gm of hemoglobin. The white-cell count was 12,000, with 82 per cent neutrophils. Many macrocytes were present, but the red cells were generally normochromic. The mean corpuscular volume was 85 cu microns, the mean corpuscular hemoglobin 20.8 micromicrogm, and the mean corpuscular hemoglobin concentration 24.4 per cent. The urine was normal. The nonprotein nitrogen was 19 mg per 100 cc. The total serum protein was 5.9 gm per 100 cc, with 3.0 gm of albumin and 2.9 gm of globulin. The serum calcium was 7.7 mg per 100 cc, the phosphorus 1.5 mg, and the alkaline phosphatase 27.5 Bodansky units. The serum bilirubin was 0.9 mg per 100 cc direct, and 1.3 mg indirect. The serum cholesterol was 156 mg per 100 cc. A cephalin flocculation test was ++ in twenty-four hours, and ++++ in forty-eight hours. The prothrombin time was 21 seconds (normal, 15 to 17 seconds). A bromsulfalein test showed 20 per cent retention. The gastric juice contained free hydrochloric acid. The stools varied

from yellow to gray, and five out of seventeen specimens were guaiac positive.

An x-ray film of the chest was essentially negative. A gastrointestinal series revealed a normal esophagus. A small portion of the fundus of the stomach protruded through a hiatus hernia but was easily reduced. The second part of the duodenum was constantly rigid in its upper portion, with an irregular filling defect and loss of mucosal pattern along its medial wall, which contained a small central ulceration (Figs 1 and 2). A questionable defect was present in the lower portion of the ascending part of the duodenal loop, where the mucosal

FIGURE 1. Roentgenogram Showing Narrowed and Rigid Area of Second Portion of Duodenum.

pattern was preserved. A barium enema was negative.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. MARSHALL K. BARTLETT: May we see the x-ray films?

DR. MILFORD D. SCHULZ: The films show a normal chest and a normal colon. In the second portion of the duodenum, however, just below the duodenal bulb and along the lesser curvature, is an area of narrowing that is quite smooth and seems to be constant. It is present in a number of films. In the central portion of this defect on two films is a

little fleck that looks like barium in a punched-out defect. This shadow corresponds to the position of the ampulla of Vater.

DR BARTLETT: Where is the other defect that was mentioned in the ascending portion?

DR SCHULZ: It must have been a fluoroscopic observation or recorded on a film that we do not have here.

DR BARTLETT: This man of fifty-six had been sick for seven weeks, at any rate that is when he first went to his doctor. We do not know how much longer he had had symptoms. He had been losing weight for six months but had had no symptoms referable to the gastrointestinal tract.

Physical examination adds that he was slightly jaundiced and had a palpable liver, which extended well below the costal margin. Quite a good deal of

FIGURE 2 Enlarged View of Region of Ampulla of Vater Showing Punched-Out Defect (arrows)

laboratory work was done — much of it because of the macrocytes seen in the smear, I presume. The various studies on the blood cells afford evidence pointing to a secondary rather than a primary anemia, although that statement is subject to correction by someone who knows more about hematology than I do. The serum bilirubin was slightly elevated, corresponding with the slight clinical jaundice. The various studies referable to the liver seem to indicate some impairment of liver function.

Certainly in a man like this we should look sharply for a malignant neoplasm somewhere. Since we are told that this man had lost 25 pounds and that his jaundice was increasing, we have to assume that it was an obstructive type of jaundice and must look for the source of the obstruction. He had had no pain, and with bleeding into the gastrointestinal tract, as shown by a positive guaiac test on repeated occasions, and a blood picture like this,

one would strongly suspect a malignant tumor. I believe that we can rule out gallstones. We have x-ray evidence that suggests a lesion in or adjacent to the duodenum that had ulcerated through into the duodenum. So as I see it, my function is to make a choice between a lesion of the ampulla or in the duodenum proper and a lesion in the head of the pancreas that had ulcerated into the duodenal wall. I do not know any way to make a sure decision. Since Dr Schulz has suggested that the lesion was in the region of the ampulla, I will put that as my first choice, with carcinoma of the head of the pancreas as the second.

DR TRACY B MALLORY: You are assuming that, if the lesion was in the ampulla, it was malignant?

DR BARTLETT: Yes.

DR JAMES H TOWNSEND: Was no attempt made to visualize the gall bladder?

DR MALLORY: A peritoneoscopy was done preoperatively. It showed a smooth, enlarged, bile-stained liver and a slightly dilated gall bladder. No fluid was found in the abdominal cavity, and a liver biopsy showed only bile stasis.

CLINICAL DIAGNOSIS

Carcinoma of head of pancreas

DR BARTLETT'S DIAGNOSIS

Carcinoma of ampulla of Vater

ANATOMICAL DIAGNOSIS

Adenocarcinoma of ampulla of Vater.

PATHOLOGICAL DISCUSSION

DR MALLORY: Dr Scannell, I believe that you operated on this man. What were your findings?

DR JOHN G SCANNELL: This man was operated on in two stages. The first consisted of drainage of the gall bladder and the establishment of a feeding jejunostomy. At that time a mass was palpated in the head of the pancreas, but its size could not be accurately determined. In two weeks we re-explored, and a small freely movable tumor was demonstrated in the head of the pancreas in the region of the ampulla; this mass was fairly readily resected. The common duct, I might add, which was not well visualized at the first exploration, was found to be tremendously dilated; the gall bladder was dilated, but the edema had completely disappeared.

DR MALLORY: At the second operation, considerable portions of the duodenum and head of the pancreas were resected. The tumor appeared to be limited to the ampulla. It involved the full thickness of the duodenal wall, but so far as we could make out it did not penetrate the pancreas. There were no obvious lymph nodes. The area of resection appeared to be entirely adequate. I do not believe that the prognosis is excellent, but it is not impossible that a cure has been effected.

DR BARTLETT: What type of tumor was it?

DR MALLORY An adenocarcinoma, fairly well differentiated. It is worth remembering in considering operation on such a patient that benign polyps of the ampulla are not extremely rare. Exploration, at least, is certainly indicated.

DR BARTLETT Was the duodenum ulcerated?

DR MALLORY There was slight ulceration of the surface of the tumor. No gross crater was evident.

DR BARTLETT What was done with the bile duct? Was the surgery complicated?

DR LELAND S MCKITTRICK I like the way that Dr Scannell passed over that.

DR SCANNELL A loop of jejunum was selected about 45 cm below the ligament of Treitz, it was transected, and the proximal end was implanted into the side of the distal portion. An end-to-end anastomosis was then effected, after the manner of Dr Allen,* between the cut ends of the common bile duct and the distal jejunum over a catheter, which was led out through the wall of the jejunum and through the abdominal wall, to be removed in about three weeks. The cut ends of the pancreas and of the stomach were then implanted into the side of this loop.

DR MALLORY Did the patient develop a pancreatic fistula?

DR SCANNELL On the tenth postoperative day he drained considerable material from the upper end of the wound, but this has since decreased to nil. From the character of the material I should judge that it was from a high jejunal or pancreatic fistula. We were unable to demonstrate the pancreatic duct at the time of exploration and therefore implanted the cut end of the pancreas into the subserosa of the jejunum.

CASE 32052

PRESENTATION OF CASE

A sixty-five-year-old woman entered the hospital complaining of abdominal pain.

For two years before admission she had had an intermittent dull ache in the right upper quadrant. The pain occasionally radiated to the back and was not associated with nausea, vomiting or anorexia. It had no relation to the ingestion of food. It lasted for about twenty-four hours, subsided and then recurred in a few days. At times she also had dull aching pain across the lower abdomen, not related to the distress in the right upper quadrant. The latter complaint was made worse by constipation but was not relieved by a bowel movement. An intermittent midepigastric distress had also been present for a year and a half. Five months before admission she was seen at another hospital, where she was told that she had a growth in the stomach. She was given a chalky milklike fluid, which she

took for three months and which seemed to relieve the epigastric pain and belching.

She had had rheumatic fever at twenty-five years of age, with no residual heart disease but with persistent joint pains. She had been known to have hypertension for fifteen years before admission and had been treated for syphilis for ten years, although she denied a history of venereal disease. Three years before admission she suddenly lost vision in the right eye, but it slowly returned. She had had three miscarriages.

The physical examination revealed a well developed and nourished woman in no acute discomfort. The pupils reacted normally to light and accommodation. The border of the heart was 11 cm to the left of the midline in the fifth interspace. A systolic murmur was heard over the aortic area. The lungs and abdomen were negative. Neurologic examination was negative.

The temperature was 97°F, the pulse 70, and the respirations 15. The blood pressure was 230 systolic, 110 diastolic.

The red-cell count was 4,200,000, with 12 gm of hemoglobin. The urine was normal. The non-protein nitrogen was 15 mg per 100 cc, and the total protein 5.9 gm. The chloride was 90 milliequiv per liter. A blood Hinton test was positive. Lumbar puncture yielded a clear fluid, with normal dynamics, the fluid contained 350 red cells per cubic millimeter. The total protein was 34 mg per 100 cc, and the gold-sol curve 0001100000.

A gastrointestinal series showed a normal esophagus and a small hiatus hernia. There was some narrowing, as well as absent peristalsis, of the prepyloric region of the stomach (Fig 1). No peristaltic waves were seen to pass through the immediate prepyloric region. It was not possible to palpate this area. There was an apparent crater about 8 mm in diameter somewhat toward the margin of the lesser curvature. The duodenal cap was small but not deformed. A barium enema showed numerous diverticula in the sigmoid. On gastroscopy the instrument passed readily. When first examined the angulus was tightly and smoothly closed, without any spasm or ropelike contraction. With air inflation the angulus opened and presented a normal appearance. Slow peristaltic waves were seen to pass over the proximal antrum, which appeared somewhat granular but was otherwise normal. The distal antrum and the pylorus were not visible. The body of the stomach appeared normal throughout.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR DANIEL S ELLIS I should like to call attention to the fact that this woman's pain was not associated with nausea, vomiting or anorexia. The history does not state whether she had these symptoms at the time of admission, yet I am forced

*Allen A W. Method of re-establishing continuity between bile ducts and gastrointestinal tracts. *Ann Surg* 121:412-424 1945.

to conclude from the chemical values given in the laboratory data that the patient had been vomiting I do not know how else to explain the low chloride and the high carbon dioxide in the absence of renal disease

I assume that the red cells in the spinal fluid were due to the trauma of the tap. We are not told the result of the spinal-fluid Wassermann test. Perhaps the test was not done. In the absence of

do not represent just a puckered and swollen stomach wall. Certainly, it is not a normal mucosal pattern.

DR ELLIS: Is that the only film of the gall bladder?

DR SCHULZ: No, but it is a representative one.

DR ELLIS: May we see a film of the chest?

DR SCHULZ: None are available.

DR ELLIS: We have, then, the story of a patient, sixty-five years of age, who we know had hypertension of some degree, with cardiac enlargement,

FIGURE 1 Roentgenogram of Stomach following Barium Meal

that information I am going to assume that the spinal fluid was normal.

From the available history there is one thing that I am sure of, namely, that an operation was a prerequisite of diagnosis.

May we see the x-ray films?

DR MILFORD D. SCHULZ: This film is put up simply to show that the colon and gall bladder were normal. This next film shows an area of irregularity in the antrum and in the prepyloric region of the stomach. This last film, I believe, shows best what was thought to have been an ulcer crater. There is apparently some rigidity about it along the lesser curvature side of the antrum and in the prepyloric region. The duodenal bulb is quite normal.

DR ELLIS: Can you see a mass in the prepyloric area?

DR SCHULZ: No.

DR ELLIS: What about the mucosal markings?

DR SCHULZ: They are not normal. Some markings look like mucosal folds, but I wonder if they

diverticulums of the sigmoid, which could account for the discomfort low in the abdomen, and a small hiatus hernia, which may or may not have contributed to her symptoms in the past. In addition, the factor of primary importance, — the one that apparently resulted in her hospitalization, — was a lesion of the stomach and, as I see it, my problem is to say what that lesion was.

It seems to me that the differential diagnosis is clear and lies between one of three things: carcinoma of the stomach, benign peptic ulcer and syphilis of the stomach. The latter diagnosis has rarely been proved. When it occurs it may resemble ulcer but is likelier to resemble carcinoma. It is usually associated with weight loss, vomiting, anorexia, anemia and achlorhydria. The criteria for a clinical diagnosis of gastric syphilis are the proper age group (usually under forty), collateral evidence of syphilis, x-ray evidence of a tubular prepyloric obstruction, improvement under anti-syphilitic therapy and a lesion found at operation with the microscopic characteristics of syphilis.

he symptoms and x-ray evidence, as well as the positive Hinton test, are the positive indications for such a diagnosis in this case. This patient, however, was in an older age group, and there is no evidence that ten years of antisyphilitic therapy had helped her stomach trouble.

On the basis of the patient's age and the location of the lesion the chances that this was a benign ulcer are remote. A benign ulcer, however, may have enough inflammatory reaction around it to give an x-ray picture such as the one we have just seen, and the fact that this patient was not anemic and was reported to be in a good state of nourishment also favors a diagnosis of a benign lesion, especially in the light of the prolonged history of symptoms and the proof of a gastric lesion of at least five months' duration.

Finally, we have to consider malignant disease of the stomach. This lesion is located in the prepyloric region, where 70 per cent of all gastric cancers are found. Twenty-five per cent of the remaining gastric tumors occur on the lesser curvature, and in this case there was an ulceration on the lesser curvature. To know whether this patient had achlorhydria and exactly how much weight she had lost would be helpful. As I said in the beginning, the one thing that I am sure of is that the only way an accurate diagnosis could have been made in this case was by operation, and even then, microscopic examination of the specimen may have been necessary.

In conclusion I shall say that I do not believe this woman had gastric syphilis or that she had a benign peptic ulcer. My final diagnosis is malignant disease of the stomach, probably an adenocarcinoma, with partial pyloric obstruction, she also had essential hypertension and hypertensive heart disease, diverticulums of the sigmoid, latent syphilis and a hiatus hernia, the last being an incidental finding and not contributing to her symptoms.

DR. TRACY B. MALLORY: Are there any comments or alternative diagnoses?

DR. JAMES A. HALSTED: Chronic gastritis might give this picture.

DR. MALLORY: Has the roentgenologist anything to say about that?

DR. SCHULZ: There is no evidence of fluid, and the gastric rugae are not greatly swollen.

DR. MALLORY: Dr. Scannell, will you tell us about the gross findings at operation?

DR. JOHN G. SCANNELL: We were intrigued by the prepyloric region at operation. The stomach was freely movable, with no gross retroperitoneal disease. There was an area of induration in the prepyloric area that involved the whole circumference of the stomach, not being limited to the lesser curvature. We thought it probably was benign disease, but we could not tell what it was. There were no enlarged lymph nodes, but since we were doing the operation for potentially malignant

disease, we removed the omentum and secured the left gastric artery at its source. On opening the resected portion of the stomach, we were still at a loss to explain the nature of the disease. There were shallow ulcerations in the mucosa, and the wall of the stomach was indurated but not adherent to surrounding structures.

DR. FRANCIS M. RACKEMAN: Was there any disturbance of the blood supply?

DR. SCANNELL: No obvious disturbance.

CLINICAL DIAGNOSIS

Carcinoma of stomach

DR. ELLIS S. DIAGNOSIS

Carcinoma of stomach

ANATOMICAL DIAGNOSIS

Lymphoblastic lymphoma of stomach

PATHOLOGICAL DISCUSSION

DR. MALLORY: The pathologist was likewise unable to decide from examination of the gross specimen whether the lesion was benign or malignant, although the latter seemed a little more probable. The diagnosis had to wait for microscopic examination, which showed a malignant infiltrative tumor that proved to be a lymphoma and not a carcinoma.

Following resection, the patient was started on x-ray therapy, and she is still in the hospital undergoing treatment. The outlook in these cases is not too bad. With a combination of resection and radiation, "cures" of five or more years sometimes occur.

DR. BENJAMIN CASTLEMAN: Were the lymph nodes involved?

DR. MALLORY: No large nodes were found.

DR. JAMES H. TOWNSEND: Do lymphomas usually ulcerate?

DR. MALLORY: They may or may not. Sometimes they produce extremely large ulcerations.

DR. FLETCHER H. COLBY: That means that a lymphoma may be localized?

DR. MALLORY: In the gastrointestinal tract it is quite frequent to find localization in the wall of the viscus, with the immediate nodes entirely negative. Even when the nodes are enlarged there is frequently no microscopic evidence of infiltration.

DR. SCHULZ: In the absence of involvement of the regional nodes or of remote disease, I wonder about the need for x-ray therapy with the lesion presumably so completely removed.

DR. MALLORY: We have a few long cures on record from surgery alone, but there are not enough of these cases to compare with those receiving the combined treatment for statistical analysis.

DR. FREDERICK KRAVES: What type of lymphoma was this?

DR. MALLORY: We classified it as a lymphoblastic lymphoma, although the cells were not extremely immature.

NATIONAL SOCIAL HYGIENE DAY

FEBRUARY 6 is National Social Hygiene Day, the tenth annual event of its kind on a national basis. It had its beginning as a series of meetings held across the country on the day of the annual meeting of the American Social Hygiene Association, being an alternate for members unable to travel to the meeting, but in 1937 it was given formal recognition by designating the day by this name. It has come to be a day on which pledges are renewed to the achievement of the high standards set by the founders of the Association. These founders had as their major objective the protection of the family and its members from the perils to health, happiness and home that result from venereal disease and prostitution. The full attainment of these aims is chiefly concerned with an attempt

to guide schoolteachers, religious leaders and parents, as well as physicians, in the furnishing of wise counsel concerning the sex problems of the younger generation. The achievement of its objective is a co-operative undertaking requiring the energies of local and national associations and groups of many types, such as health departments, social agencies, physicians, nurses, educators, church leaders and Army and Navy venereal-disease control centers, for its successful completion.

Great advances have been made in these ten years in the fields of diagnosis and treatment of syphilis and gonorrhea. The dramatic success of penicillin as a therapeutic agent is still unfolding, but the final estimate of its value, especially in syphilis, can only be measured by medical experience with the drug over a period of years. In the meantime the early diagnosis of syphilis and gonorrhea is essential. The campaign for the prevention of these diseases must proceed with increased vigor. Education, that is, education of the patient, the family and the public at large, is the essential feature of any preventive program directed at these diseases. The publication of a recent study by the Advisory Committee on Public Education for the Prevention of Venereal Disease of the United States Public Health Service* occurred at an opportune moment. Among the recommendations of this committee three items should be emphasized: first, that venereal-disease education is a primary responsibility of official health agencies and should be conducted by them on an intensive and a sustained basis; second, that this education should be coordinated with other health-education programs; and third, that there should be a considerable expansion of facilities for training health-department personnel who are to engage in these activities.

Participation of the physician in this campaign for the protection of the individual and the family obviously demands early diagnosis, adequate treatment and the routine reporting of cases of venereal disease, as directed by the laws of his state. As a citizen as well as a physician he has a large obligation, by reason of his medical knowledge, to participate to the fullest extent in organized activities.

*Report of United States Public Health Service Advisory Committee on Public Education for the Prevention of Venereal Diseases (July 1945). *J. Fam. Dis. Inform.* 26:256-263, 1945.

the education of the public and the prevention these infections, in accordance with the plans developed by public-health departments and associations dedicated to this cause

ELSE WHENCE THIS PLEASING HOPE"

MUCH has been written on the medical and surgical care of the patient, volumes have been published on the treatment of the mentally ill, but little has been said and even less has been written on the psychologic aspects of patients who are gravely ill or who are suffering from a fatal disease. An excellent approach to this subject has come from the pen of a layman, Ben Ames Williams,* who, to his discomfiture but to the advantage of the public, has contrived from time to time to become ill. He has been able, therefore, "To see ourselves as others see us" and to point out to us doctors the psychologic pitfalls that lie before us, but in addition he has given some very constructive and valuable advice concerning their avoidance. To those who have not read his article, we recommend it, to those who have, we suggest that they read it again.

In last week's issue of the *Journal* appeared the concluding paper of a series of articles on Hodgkin's disease, and therein are contained a few words of advice concerning the psychologic care of patients with a disease that is almost always but not invariably fatal. Of the last six words of the previous sentence the most important, far and away, are "but not invariably" for in these words lie one of the subtle secrets of the care of the patient.

What have we to offer to patients with this condition or allied ones? X-ray therapy, certainly, transfusions, probably, radical surgical intervention, rarely. Can we offer the hope of a true cure? Yes,

but only once in hundreds of cases. Yet, who can predict in the individual case, granting that it be early, whether or not a cure will result. Herein lies the second secret.

Above all we can offer hope. That we can and must give in order that the patient's days, whether they be short or long, be ever full of hope, not despair. Nearly three years ago a young soldier who had been through the Kasserine Pass both ways was suddenly invalided home for reasons quite

unknown to him, because he felt perfectly well. In the States he was with equal abruptness and greater bluntness told "the truth" — that he had leukemia, that he would live but a few months and that nothing could be done. Shortly after he was boarded out with a Certificate of Disability Discharge, he consulted a civilian doctor. From him he received hope, and the tense, distraught, despairing,

MASSACHUSETTS MEDICAL SOCIETY POSTWAR LOAN FUND

frightened soldier became a happy, hopeful young man. No diagnosis was mentioned. Rather it was stressed that much could and would be done and that he could reasonably look forward to an active and useful life. Indeed, his illness was so minimized that the patient came, quite surely, to believe that he did not have leukemia. Two years later he rather shyly slipped into his physician's hand a newspaper clipping about a new cure for leukemia. "I just thought I would ask if there is anything in that, doctor." "No, I'm afraid there isn't." No more was said. The boy had grown to know the truth, but its impact was gone because of the insidiousness of its realization. Today, three years and more after the battle of the Kasserine Pass, that boy is alive and happy and active. The diagnosis, if the real truth be known, is not entirely clear, but the facts are as stated. Hope we can give, the patient's burdens we can, to a great extent, take unto ourselves.

*Williams B. A. The Greeks had a word for it. *New Eng J Med* 233:427-432, 1945

But it is not always the patient who must be treated with gentleness it is not always the patient in whom we must, at all costs, inspire hope. He may be quite oblivious of the truth while his friends or relatives may be distracted almost beyond control. Then we must turn our attention to these good people, if only to protect the patient.

If we are to give hope we must learn the gentle art of evasion — not lying, mind you, but evasion. Recently an extremely astute man with some knowledge of medicine and indeed of his own disease, aplastic anemia, asked his physician point blank "Does it not follow, doctor, because my general health and sense of well being have greatly improved in the past two weeks and because the ulcerations in my mouth have entirely cleared, that my anemia will similarly improve?" It did not follow in the slightest. But cannot we reply without hesitation — to hesitate is to fail — that we hope that such will be the case and pass rapidly on to less contentious matters before the patient recognizes that we have said "hope" not "will"? That patient died ten days later at home, having in the meantime spent three days with friends in New York City. He had no wish to hurry home. Was he not filled with hope?

NOTICES

ANNOUNCEMENTS

Dr. Sawyer Foster is resuming the practice of internal medicine at 144 Commonwealth Avenue, Boston.

Dr. George A. Marks, having returned from military service, announces the reopening of an office at 1101 Beacon Street, Brookline, for the practice of surgery.

Dr. Edward T. Moses, having returned from active service with the United States Army, has opened his office at 632 Main Street, Malden, for the practice of neuropsychiatry.

Dr. Jules H. Shaw announces his return from military service and the opening of offices at 510 Commonwealth Avenue, Boston, for the practice of ophthalmology.

Dr. Howard B. Sprague, having returned from active duty in the United States Navy, is resuming the practice of cardiology at 270 Commonwealth Avenue, Boston.

Dr. Ralph Volk, having completed active service with the United States Navy, announces his return to the practice of medicine at 1411 Beacon Street, Brookline.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, February 19, at 8:15 p.m. Dr. Edwin J. Cohn and Dr. Charles A. Janeway will speak on the subject "The Chemical Separation and the Clinical Appraisal of the Components of the Blood."

TUFTS ALPHA OMEGA ALPHA

The Tufts chapter of the Alpha Omega Alpha will meet in the Auditorium of the Beth Israel Hospital, Boston, on Wednesday, February 27, at 8:30 p.m. Dr. George R. Mize will speak on the subject "The Art of Medicine."

PRIZE CONTEST

The American Association of Obstetricians, Gynecologists and Abdominal Surgeons Foundation has recently announced that the annual prize contest will be conducted again this year. Requests for detailed information should be addressed to the secretary, Dr. James R. Bloss, 418 Eleventh Street, Huntington 1, West Virginia.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, FEBRUARY 7

- FRIDAY, FEBRUARY 8**
 *9:00-10:00 a.m. Medical clinic. Isolation Amphitheater, Children's Hospital.
 *9:00-10:00 a.m. Physiologic Evaluation of Quartermaster Clothing and Equipment. Colonel John H. Talbot. Joseph H. Pratt Diagnostic Hospital.
 *10:00 a.m.-12:00 m. Medical staff rounds. Peter Bent Brigham Hospital.
 10:50 a.m. Rationale of Pharmacology in Dermatology. Professor L. M. Ohmart (Postgraduate clinic in dermatology and syphilology) Amphitheater, Dowling Building Boston City Hospital.
 12:00 m.-1:00 p.m. Clinicopathological conference (Boston Floating Hospital) Joseph H. Pratt Diagnostic Hospital.
MONDAY, FEBRUARY 11
 *12:00 m.-1:00 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.
TUESDAY, FEBRUARY 12
 *9:00-10:00 a.m. Medical clinic. Infants' Hospital.
 *12:15-1:15 p.m. Clinicorontogenological conference. Peter Bent Brigham Hospital.
 8:00 p.m. Harvard Medical Society. Peter Bent Brigham Hospital.
WEDNESDAY, FEBRUARY 13
 *9:00-10:00 a.m. The Treatment of Laennec Cirrhosis. Dr. Roy C. Crosby. Joseph H. Pratt Diagnostic Hospital.
 *12:00 m. Clinicopathological conference. Children's Hospital.
 *12:00 m.-1:00 p.m. Clinicopathological conference. Cambridge Hospital.
 *7:15 p.m. Graduate seminar in pediatrics. Children's Medical Service Amphitheater 3A Massachusetts General Hospital.
 *Open to the medical profession.

SILENT AND MASQUERADING INTRATHORACIC LESIONS*

The Importance of Proper Identification of Lesions Discovered during X-Ray Surveys

RICHARD H. OVERHOLT, M.D.,† AND NORMAN J. WILSON, M.D.

BOSTON

MILLIONS of persons have recently had their chests x-rayed in the mass surveys of large segments of the population now under way. The program at induction centers and in the armed forces, industrial plants and schools is well known. In addition, some form of radiologic screening of the chest is becoming a routine procedure in many clinics and hospitals and in the private practice of many physicians. Thousands of pathologic lesions have been discovered in apparently healthy persons, a large percentage being in the minimal stage, when treatment offers the best chance of cure.

Of this group, the patient who presents one of the most difficult and important problems is the one with a lesion of the chest demonstrated by x-ray and associated with either no symptoms or those so mild that its seriousness and potentialities are unsuspected. These cases present a grave problem to the medical profession. Surveys find, but do not necessarily identify, disease. The proper identification and successful treatment of these early forms of intrathoracic disease demand serious attention.

There is evidence that the danger and the immediate threat of such lesions are too little appreciated. Waiting for time to tell the story is still prevalent. All too often the physician reassures his patient and asks him to return in a few months for a checkup, only to find at that time that a minimal tuberculous focus has developed into moderately advanced or far-advanced disease, or that a small tumor has either metastasized or extended so that it is no longer operable. Roentgenologists likewise frequently advise checkups in a few months in the face of disease processes that carry an immediate and dangerous threat. In the light of present diagnostic and therapeutic possibilities, time becomes a deadly enemy for many patients with intrathoracic lesions.

Recently Goorwitch¹ analyzed the effects of mass surveys in Los Angeles County, California, on the extent of pulmonary involvement in tuberculous males admitted to the Olive View Sanatorium. Although approximately two thirds of the lesions so found were minimal, no reduction occurred in the incidence of far-advanced disease among those entering the sanatorium. Goorwitch explained this by the fact that only a small percentage of those with minimal involvement were admitted. Such statistics leave unanswered the question of what has happened to the thousands of patients with minimal lesions uncovered in surveys and in private practice. To be sure, some of these are lost in the shuffle. Others refuse to enter a sanatorium for treatment. The histories of such cases, however, all too frequently point to the failure of physicians to appreciate the seriousness of the early lesion as the direct cause of the patient's delay in entering the sanatorium for proper treatment.

The same state of affairs exists with carcinoma of the lung. In 1942, Overholt² reviewed 153 such cases. Sixty per cent of these patients were not only incorrectly diagnosed by the first physician consulted but were treated on the basis of that diagnosis for long periods of time, an average of twelve months intervening between the onset of symptoms and the establishment of the proper diagnosis. In the average case the physician did not request an x-ray examination for three months after onset, and the correct diagnosis was not made for six months after the pulmonary lesion had been demonstrated by x-ray.

The foregoing facts establish the need for fundamental concepts concerning the diagnosis, evaluation and therapy of intrathoracic lesions. Naturally, the entire subject cannot be covered in a single paper of this kind, and only three outstanding types of condition uncovered in mass surveys will be considered — tuberculosis, carcinoma of the lung and mediastinal tumors.

*From the New England Deaconess Hospital.

†Thoracic surgeon, New England Deaconess Hospital.

But it is not always the patient who must be treated with gentleness it is not always the patient in whom we must, at all costs, inspire hope. He may be quite oblivious of the truth while his friends or relatives may be distracted almost beyond control. Then we must turn our attention to these good people, if only to protect the patient.

If we are to give hope we must learn the gentle art of evasion — not lying, mind you, but evasion. Recently an extremely astute man with some knowledge of medicine and indeed of his own disease, aplastic anemia, asked his physician point blank "Does it not follow, doctor, because my general health and sense of well being have greatly improved in the past two weeks and because the ulcerations in my mouth have entirely cleared, that my anemia will similarly improve?" It did not follow in the slightest. But cannot we reply without hesitation — to hesitate is to fail — that we hope that such will be the case and pass rapidly on to less contentious matters before the patient recognizes that we have said "hope" not "will"? That patient died ten days later at home, having in the meantime spent three days with friends in New York City. He had no wish to hurry home. Was he not filled with hope?

NOTICES

ANNOUNCEMENTS

Dr. Sawyer Foster is resuming the practice of internal medicine at 144 Commonwealth Avenue, Boston.

Dr. George A. Marks, having returned from military service, announces the reopening of an office at 1101 Beacon Street, Brookline, for the practice of surgery.

Dr. Edward T. Moses, having returned from active service with the United States Army, has opened his office at 632 Main Street, Malden, for the practice of neuropsychiatry.

Dr. Jules H. Shaw announces his return from military service and the opening of offices at 510 Commonwealth Avenue, Boston, for the practice of ophthalmology.

Dr. Howard B. Sprague, having returned from active duty in the United States Navy, is resuming the practice of cardiology at 270 Commonwealth Avenue, Boston.

Dr. Ralph Volk, having completed active service with the United States Navy, announces his return to the practice of medicine at 1411 Beacon Street, Brookline.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, February 19, at 8:15 p.m. Dr. Edwin J. Cohn and Dr. Charles A. Janeway will speak on the subject "The Chemical Separation and the Clinical Appraisal of the Components of the Blood."

TUFTS ALPHA OMEGA ALPHA

The Tufts chapter of the Alpha Omega Alpha will meet in the Auditorium of the Beth Israel Hospital, Boston, on Wednesday, February 27, at 8:30 p.m. Dr. George R. Mearns will speak on the subject "The Art of Medicine."

PRIZE CONTEST

The American Association of Obstetricians, Gynecologists and Abdominal Surgeons Foundation has recently announced that the annual prize contest will be conducted again this year. Requests for detailed information should be addressed to the secretary, Dr. James R. Bloss, 418 Eleventh Street, Huntington 1, West Virginia.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, FEBRUARY 7

- FRIDAY, FEBRUARY 8
 *9:00-10:00 a.m. Medical clinic. Isolation Amphitheater Children's Hospital.
 *9:00-10:00 a.m. Physiologic Evaluation of Quartermaster Clothing and Equipment. Colonel John H. Talbot. Joseph H. Pratt Diagnostic Hospital.
 *10:00 a.m.-12:00 p.m. Medical staff rounds. Peter Bent Brigham Hospital.
 10:50 a.m. Rationale of Pharmacology in Dermatology. Professor L. M. Ohmart (Postgraduate clinic in dermatology and syphilology). Amphitheater, Dowling Building. Boston City Hospital.
 12:00 p.m.-1:00 p.m. Clinicopathological conference (Boston Post Hospital). Joseph H. Pratt Diagnostic Hospital.
 MONDAY, FEBRUARY 11
 *12:00 p.m.-1:00 p.m. Clinicopathological conference. Peter Bent Brigham Hospital.
 TUESDAY, FEBRUARY 12
 *9:00-10:00 a.m. Medical clinic. Infants' Hospital.
 *12:15-1:15 p.m. Clinicoroeptigenological conference. Peter Bent Brigham Hospital.
 8:00 p.m. Harvard Medical Society. Peter Bent Brigham Hospital.
 WEDNESDAY, FEBRUARY 13
 *9:00-10:00 a.m. The Treatment of Laennec Cirrhosis. Dr. Roy C. Crosby. Joseph H. Pratt Diagnostic Hospital.
 *12:00 p.m. Clinicopathological conference. Children's Hospital.
 *12:00 p.m.-1:00 p.m. Clinicopathological conference. Cambridge Hospital.
 *7:15 p.m. Graduate seminar in pediatrics. Children's Medical Service Amphitheater 3A Massachusetts General Hospital.
 *Open to the medical profession.

 MAY 8 Annual meeting.

physician not only at once to guard patients with innocuous lesions against long periods of unnecessary therapy, but — what is more important — to protect those with active lesions by giving prompt and energetic treatment

Evaluation of the Patient

The evaluation of the patient who harbors the tuberculous focus is of prime importance. The age, sex, race and socioeconomic status are the chief factors to be considered.²

Age The evidence gained in mass surveys and in the study of serial x-ray films demonstrates that early tuberculous infiltration usually occurs between adolescence and the age of thirty. These lesions represent a focus of tuberculous bronchopneumonia, with a predominant tendency toward central caseation, excavation and bronchial spread. They constitute an immediate threat, and therapy must therefore be prompt and adequate. In the later decades of life, more of the chronic productive fibroid forms of tuberculosis are seen. Some of these patients require therapy because of residual or renewed activity. In others the lesion has been stable for many years and requires no therapy. In the latter type of case a period of watchful waiting is justifiable provided that complete studies have failed to show any signs of activity.

Sex It is also during the second and third decades that the factor of sex exerts its strongest influence. Tuberculosis in young women tends to be more active and fatal than in men of the same age group.

Race Although the influence of race is strongly disputed, there can be little doubt that under existing circumstances in most communities Negroes exhibit a lower resistance to tuberculosis than do Whites. This is evidenced by their greater tendency to develop acute pneumonic lesions and by their predisposition to dissemination of the infection through the lymphatics and blood stream.

Socioeconomic factors The patient's occupation and station in life also influence the prognosis. Clinical and epidemiologic studies show that poverty and debilitating working conditions are likely to be associated with progressive tuberculosis.

These factors are vital not only in evaluating the lesion but in prescribing treatment, because they render both steps possible on the basis of the underlying lesion. The clinical data must be interpreted pathologically if judgment is to be accurate and treatment adequate.

Study of the Sputum

When a positive sputum has been found in a patient with a pulmonary infiltration, not only

has the diagnosis been confirmed but the need for active therapy has been established. Any lesion shedding tubercle bacilli harbors some activity. Nevertheless, it must be emphasized that a positive sputum is not a prerequisite for a diagnosis of pulmonary tuberculosis and that a negative sputum does not necessarily rule out activity. A positive sputum may never be demonstrated in inactive lesions and in many active ones of minimal extent. It has been repeatedly shown, however, that a sufficiently rigid study of the sputum will show it to be positive in the vast majority of active tuberculous lesions.

Two factors influence the accuracy of sputum examinations — the length of time over which the specimens have been collected and the method by which they have been examined. The examination of single specimens by the routine smear method is notoriously unreliable. In fact it is so inefficient that its use as a diagnostic procedure should be condemned. The use of a concentration technic increases positive findings by about 30 per cent. Pooled specimens the sputum having been collected from two to seven days further increase positive results. Multiple cultures and guinea-pig inoculations of pooled specimens should always be employed before one concludes that the sputum is negative. In the event that sputum cannot be produced, a study of gastric washings usually reveals the presence of tubercle bacilli if the pulmonary process is active. Secretions from the lungs that are carried to the upper air passages by ciliary motion of the mucosa and by gravity are swallowed during sleep so that the gastric specimen should be taken in the morning and before breakfast. Acid-fast organisms that are not tubercle bacilli are frequently found in the gastric specimen. For this reason, they should be identified by culture and guinea-pig inoculation.

Pinner and Werner¹ state that over 99 per cent of patients with active tuberculosis are found to have tubercle bacilli in secretions from the lungs if all methods of examination are utilized. Thus, when these tests are repeatedly negative in a patient with a progressive pulmonary infiltration the lesion is probably nontuberculous and other diagnostic procedures are indicated. For example, we have proved the presence of primary cancer in a considerable number of sputum-negative patients who had been treated for months for tuberculosis by bed rest and even pneumothorax.

Leukocytic Index and Erythrocyte Sedimentation Rate

An altered leukocytic index or an elevated erythrocyte sedimentation rate usually indicates activity of the tuberculous lesion. Here again, however it must be emphasized that an active, progressive tuberculous focus may produce too little systemic reaction to cause any abnormality in either of these findings. In fact the vast majority

TUBERCULOSIS

The evaluation of tuberculous lesions of small or moderate extent that are either asymptomatic

an immediate threat or may be predominantly fibrotic and calcific, in which event the danger is more remote. They may be stationary, retrogress-

FIGURE 1 Case 2094

A 20-year-old, married woman, was first seen in March, 1942, complaining of fatigue, low-grade fever and wheezing in the left side of the chest of 3 months' duration. She had been treated for bronchitis with sulfadiazine. A roentgenogram of the chest taken at this time (upper left) revealed a small area of infiltration in the left 2nd interspace. A sputum examination was not performed, and the patient was advised to return in 3 months for another x-ray examination of the chest. A chest x-ray film taken June 9 (upper right) showed little, if any, significant changes, and the patient's symptoms and general condition had not changed since the time of her first examination three months earlier. In a film taken July 30 (lower left) just six weeks later, there was a mediastinal shift, and increased density at the left base was interpreted as atelectasis; the infiltration in the left upper lobe had also increased. The patient's symptoms had increased, and a bronchoscopy revealed a marked tuberculous ulcer stenosis of the left main bronchus, the sputum was positive. A left pneumonectomy was performed, and the patient is living and well today, with a persistently negative sputum. In the surgical specimen (lower right) the entire left lower lobe was literally riddled with caseous nodules and numerous areas of caseation were also present in the upper lobe; there was no cavity. Comment: This case illustrates pulmonary tuberculosis masquerading as "asthmatic bronchitis." It also demonstrates rapid progression of disease within the space of a few weeks, which was the direct result of the bronchial lesion in this particular case. A sputum examination early in the course of the patient's illness would have established the diagnosis and would have brought her under proper treatment. This possibly might have averted the marked spread of the tuberculosis.

or produce extremely mild symptoms presents a serious and difficult problem. These lesions may form early exudative, caseous foci and thus carry

sive or progressive. The basic problem is that of proving the inactivity or activity of the demonstrated x-ray lesion. It becomes the duty of the

physician not only at once to guard patients with nocuous lesions against long periods of unnecessary therapy, but — what is more important — to protect those with active lesions by giving prompt and energetic treatment

Evaluation of the Patient

The evaluation of the patient who harbors the tuberculous focus is of prime importance. The age, sex, race and socioeconomic status are the chief factors to be considered.³

Age The evidence gained in mass surveys and in the study of serial x-ray films demonstrates that early tuberculous infiltration usually occurs between adolescence and the age of thirty. These lesions represent a focus of tuberculous bronchopneumonia, with a predominant tendency toward central caseation, excavation and bronchial spread. They constitute an immediate threat and therapy must therefore be prompt and adequate. In the later decades of life, more of the chronic productive fibroid forms of tuberculosis are seen. Some of these patients require therapy because of residual or renewed activity. In others the lesion has been stable for many years and requires no therapy. In the latter type of case a period of watchful waiting is justifiable provided that complete studies have failed to show any signs of activity.

Sex It is also during the second and third decades that the factor of sex exerts its strongest influence. Tuberculosis in young women tends to be more active and fatal than in men of the same age group.

Race Although the influence of race is strongly disputed there can be little doubt that under existing circumstances in most communities Negroes exhibit a lower resistance to tuberculosis than do Whites. This is evidenced by their greater tendency to develop acute pneumonic lesions and by their predisposition to dissemination of the infection through the lymphatics and blood stream.

Socioeconomic factors The patient's occupation and station in life also influence the prognosis. Clinical and epidemiologic studies show that poverty and debilitating working conditions are likely to be associated with progressive tuberculosis.

These factors are vital not only in evaluating the lesion but in prescribing treatment, because they render both steps possible on the basis of the underlying lesion. The clinical data must be interpreted pathologically; if judgment is to be accurate and treatment adequate.

Study of the Sputum

When a sputum has been found in a patient with pulmonary infiltration not only

has the diagnosis been confirmed but the need for active therapy has been established. Any lesion shedding tubercle bacilli harbors some activity. Nevertheless it must be emphasized that a positive sputum is not a prerequisite for a diagnosis of pulmonary tuberculosis and that a negative sputum does not necessarily rule out activity. A positive sputum may never be demonstrated in inactive lesions and in many active ones of minimal extent. It has been repeatedly shown, however, that a sufficiently rigid study of the sputum will show it to be positive in the vast majority of active tuberculous lesions.

Two factors influence the accuracy of sputum examinations — the length of time over which the specimens have been collected and the method by which they have been examined. The examination of single specimens by the routine smear method is notoriously unreliable. In fact, it is so inefficient that its use as a diagnostic procedure should be condemned. The use of a concentration technic increases positive findings by about 30 per cent. Pooled specimens, the sputum having been collected from two to seven days, further increase positive results. Multiple cultures and guinea-pig inoculations of pooled specimens should always be employed before one concludes that the sputum is negative. In the event that sputum cannot be produced a study of gastric washings usually reveals the presence of tubercle bacilli if the pulmonary process is active. Secretions from the lungs that are carried to the upper air passages by ciliary motion of the mucosa and by gravity are swallowed during sleep so that the gastric specimen should be taken in the morning and before breakfast. Acid-fast organisms that are not tubercle bacilli are frequently found in the gastric specimen. For this reason they should be identified by culture and guinea-pig inoculation.

Pinner and Werner⁴ state that over 99 per cent of patients with active tuberculosis are found to have tubercle bacilli in secretions from the lungs if all methods of examination are utilized. Thus, when these tests are repeatedly negative in a patient with a progressive pulmonary infiltration the lesion is probably nontuberculous and other diagnostic procedures are indicated. For example, we have proved the presence of primary cancer in a considerable number of sputum-negative patients who had been treated for months for tuberculosis by bed rest and even pneumothorax.

Leukocytic Index and Erythrocyte Sedimentation Rate

An altered leukocytic index or an elevated erythrocyte sedimentation rate usually indicates activity of the tuberculous lesion. Here again, however, it must be emphasized that an active, progressive tuberculous focus may produce too little systemic reaction to cause an abnormality in either of these findings. In fact, the vast majority

of early lesions are associated with no change in the leukocytic index and no elevation of the sedimentation rate, so that these laboratory tests are of value only when they show abnormality

Evaluation of the Roentgenogram

It is evident that the clinical evaluation of the patient and the study of the sputum, leukocytic index and erythrocyte sedimentation rate establish the activity of the pulmonary lesion in some cases. An extremely important group remains in which

of the x-ray shadow strongly indicates the presence of activity. Most dense and homogeneous lesions with ill-defined, fuzzy edges are exudative. More frequently, the activity of the process is indicated by serial roentgenograms. Any change, whether it be progression or resolution, indicates an active lesion. It is essential to realize that such foci resolve to a point at which little or no change is discernible from month to month, and yet remain a constant threat because of residual foci of caseation. After the x-ray fails to reveal any change in the lesion it re-

FIGURE 2 Case 2194

This 41-year-old single woman was first seen in October, 1942. A mass in the right upper lobe (upper left) had been discovered elsewhere in May, 1939 and had been followed by periodic chest x-ray films. The patient had always been asymptomatic. Repeated sputum examinations were negative, as was bronchoscopy. Bronchography revealed no distortion of the bronchi in the right upper lobe. The serial x-ray films (lower left) had shown a gradual increase in size of the mass, and an exploratory thoracotomy was advised. At operation on November 12, a large mass was found in the right upper lobe. No lymph nodes were palpable, but a few nodules were felt in the surrounding lung tissue. A diagnosis of tuberculoma was made, and a right upper lobectomy was performed. The patient had an uneventful postoperative course, and she is now asymptomatic, well and working. The surgical specimen (right) showed a large tuberculoma, and pathological examination revealed this mass to be incompletely encapsulated. Two areas of softening in the caseous mass were found, and numerous small tuberculous foci were seen in the surrounding parenchyma. The bronchial lymph nodes showed tuberculous involvement. Comment: This tumor in the right upper lobe was discovered by routine x-ray examination, but the diagnosis remained uncertain until proved at the time of exploratory thoracotomy.

the only significant evidence of trouble is the lesion demonstrated on the x-ray film. Once a single survey film has located an abnormal shadow, it is necessary to follow up this examination with a more comprehensive x-ray study. Fluoroscopy, stereoscopic exposures, spot films and oblique exposures often yield additional information. The precise location in respect to pulmonary segments should be determined, and the size and character of the abnormal shadow in all its dimensions should be known at the beginning. At times the character

quires months, and frequently years, for the processes of healing and fibrous encapsulation to become sufficiently firm to offer adequate protection against reactivation.

It cannot be too strongly emphasized that a minimal tuberculous lesion causing no symptoms, no abnormal physical findings and no alteration of the leukocytic index or erythrocyte sedimentation rate can be, and frequently is, an early focus of disease with serious potentialities and representing an immediate threat.

treatment

Needless to state any patient with a positive sputum or clinical evidence of activity requires immediate treatment. It is not the purpose of this discussion to consider in detail the various types of therapy; rather, because of the larger number of minimal lesions in the cases under discussion, it seems timely to restate the fundamental concepts of the treatment of the minimal and more particularly the early tuberculous lesion. The following concepts are not original but have been proved over and over again by many studies of the pathogenesis, pathology, resolution and clinical aspects of early tuberculous infiltrations.

The most opportune time to treat tuberculosis is during the phase of the early lesion when resolution and complete healing are more nearly possible and more easily accomplished than in any later phase of the disease process. The early infiltration tends to caseate and spread, and this is what happens in the majority of untreated cases. On the other hand, most cases treated by strict bed rest undergo resolution and healing.⁵

Progression of such an early minimal lesion may be extremely rapid, with moderately advanced or far-advanced disease resulting in as short a time as a few weeks.⁶ The younger the patient, the greater is the possibility of rapid progression. Thus, any lesion in a teen-age person or a young adult should be considered active until proved otherwise by a long period of observation, during which frequent x-ray films should be taken at intervals not exceeding every two weeks. In any case, regardless of age, a policy of watching the lesion with the patient carrying on his normal activities is justifiable only when the lesion is fibrotic and inactive beyond any doubt. To wait for a minimal lesion to spread to prove its activity is to court disaster, for such a procedure not only lengthens and complicates the course of treatment but jeopardizes the patient's chances of recovery.

All patients with early tuberculous lesions should be treated promptly and energetically with strict bed rest, preferably in a sanatorium. The younger the patient, the more rigid and prolonged the treatment should be. The vast majority of early lesions resolve and heal with this treatment. If progression occurs, other measures, such as pneumothorax, may be indicated. It seems important to re-emphasize the need for x-ray films taken at intervals of one or two weeks during the first several months because such lesions may spread rapidly. Treatment should be continued for many months after all clinical, laboratory and x-ray evidence of activity have disappeared. This rule is based on the fact that the resolution and fibrous encapsulation of a tuberculous focus are slow processes and continue for at least a few years, during which time any factor that upsets the patient's general resistance is likely to cause an exacerbation.

In 1937, Amberson⁵ reported his experiences with x-ray surveys and the treatment of pulmonary tuberculosis in student nurses at Bellevue Hospital, New York City, over a six-and-a-half year period. In this paper he told a story to which all physicians should listen attentively. They need look no further for the proper treatment of the early tuberculous lesion. Amberson states:

All tuberculosis appearing in student nurses has been discovered early, usually in the form of the early infiltration. Progression or relapse of the lesion in spite of rest treatment has occurred in less than 5 per cent of the cases. All who have completed treatment were able to work, and there have been no deaths from tuberculosis.

This study emphasizes the fundamentals of successful treatment of the early tuberculous focus — early discovery of the lesion and prompt, energetic and prolonged treatment, with bed rest and the judicious supplementary use of collapse measures.

CARCINOMA OF THE LUNG

Carcinoma of the lung is a problem that should be of concern to every physician. Statistics show that it represents over 10 per cent of all cases of carcinomas coming to autopsy. In Koletsky's study⁷ of 7685 autopsies, the lung was the second most frequent site of primary cancer, being exceeded only by the stomach. Jaffé⁸ in a study of 6800 autopsies found it in the third place, with the stomach in the first place and the intestine in the second. All evidence points to an absolute as well as a relative increase in incidence. At least 15,000 people in the United States die each year from cancer of the lung.²

Clinical Factors

Carcinoma of the lung, like cancer elsewhere in the body, is a disease of later life, occurring most frequently in persons over forty years of age. It is, however, by no means rare in the fourth decade, and it is occasionally seen in younger patients. It is predominantly a disease of the male sex, being at least four times as frequent in men as in women.

Primary carcinoma of the lung is bronchiogenic in origin. Thus, the signs and symptoms are the results of three processes — local irritation and destructive processes in the bronchus itself, varying degrees of bronchial occlusion and secondary changes in the lung parenchyma. In the very early stages, when the degree of bronchial occlusion is small, the x-ray examination is likely to be negative, as is the physical examination. Although symptoms may be absent at such a time, experience has shown that they tend to occur quite early in the disease. Those oftenest seen at this stage are an irritative, nonproductive, persistent cough and hemoptysis, but localized wheezing is not infrequent. At times, a metastasis from a small tumor is the cause of the first symptoms noted. As the tumor enlarges and the degree of bronchial occlusion becomes greater, the x-ray and physical findings fre-

FIGURE 3 Case 2103

This 44-year-old man had complained of slight cough for several years, which was attributed to excessive smoking. In March, 1942, the sputum became blood-streaked. On the basis of the roentgenogram taken on March 18 (upper left), a diagnosis of pulmonary tuberculosis was made in spite of a persistently negative sputum. A roentgenogram taken two months later (upper right) showed progression of disease. The sputum was still negative, but the patient was still being treated for pulmonary tuberculosis. On the basis of a roentgenogram taken on July 28 (lower left), four months after the initial roentgenogram, a diagnosis of tumor was made, and the following month the patient was referred for surgical treatment. Bronchoscopy was negative. Exploratory thoracotomy revealed a large tumor in the right upper lobe, with metastases to the bronchial lymph nodes. No mediastinal nodes were palpable. A palliative right pneumonectomy was performed. The patient made an uneventful recovery and remained well until December, when he developed evidences of metastatic disease, with death in February, 1943. The surgical specimen (lower right) was a Grade III epidermoid tumor, with metastases to the bronchial lymph node. At the time of autopsy, metastases were found in the spleen, the left adrenal gland and the peritracheal and supraclavicular lymph nodes. Comment: This case demonstrates bronchiogenic carcinoma masquerading as pulmonary tuberculosis in its early stages. The persistently negative sputum, with a changing x-ray lesion, should have aroused suspicion and indicated further diagnostic procedures. An exploratory thoracotomy at the time of the first roentgenogram would have settled the diagnosis, and pneumonectomy would have offered a better chance of cure. Attention is called to the fact that bronchoscopy was negative even at the time of operation, when metastases had already occurred. This emphasizes the limitations of bronchoscopy in the early diagnosis of bronchiogenic carcinoma and the necessity for exploratory thoracotomy.

uently indicate an obstructive emphysema of lobular, lobar or multilobar extent. More complete bronchial occlusion leads to atelectasis of similar segments of the lung. If this persists superimposed infection of the involved parenchyma is the rule.

The x-ray manifestations depend on four factors — the type and location of the tumor, the degree of bronchial occlusion, whether infection of the parenchyma has occurred and whether mediastinal or chest wall extension has taken place. In the early stages, the most frequent x-ray findings are obstructive emphysema or atelectasis of lobular, lobar or multilobar extent. Less often, the tumor itself is seen — notably when it has originated in the periphery of the bronchial tree. Evidence of infection may be superimposed early. Extension to the mediastinum and chest wall, although certainly not a part of the early pathologic life of the tumor, sometimes occurs early in the clinical course.

From this incomplete consideration of bronchiogenic tumors, it can be seen that most of the symptoms usually listed as those produced by carcinoma of the lung, such as pain, excessive sputum, weight loss and cachexia, are as a rule not a part of the early picture. They are the result of extension of the tumor, secondary changes of lung parenchyma and the systemic reaction to both these processes. More frequently, the x-ray film shows definite changes, yet the symptoms are so mild as to cause little suspicion of such a serious underlying lesion. The latter type of case is the one oftenest seen in the early stages in survey work and clinical practice, and is the one on which we wish to focus attention. Most patients are men past middle age with a demonstrated x-ray lesion, accompanied by no symptoms or by mild ones. In many cases the only symptom is a mild cough, which is attributed to cigarette smoking. The clinical picture may mimic that of any of the ordinary diseases of the lungs. The x-ray manifestations may be indistinguishable from those of tuberculosis, bronchiectasis, unresolved pneumonia or suppurative disease. Such patients present a serious problem and one that demands immediate solution. If the lesion is caused by carcinoma, speed in diagnosis and surgical extirpation offer the only chance for cure. In no other disease process is time so dangerous an enemy. Early diagnosis and radical treatment in the early stage frequently lead to successful therapy. Without exception a policy of watchful waiting leads to ultimate death.

Thus, any patient, especially one past middle age, with persistent pulmonary symptoms or an unexplained x-ray lesion* should be immediately subjected to a series of diagnostic tests to prove or disprove the existence of cancer. Whenever

possible, tissue should be secured for pathological study, since this is the only sure way to establish the diagnosis.

Diagnostic Procedures

Search for peripheral metastasis. Careful examination of the cervical lymph nodes and the skin for evidence of metastasis should be made, and suspicious nodes or skin nodules should be removed for pathological study. If the biopsy is positive the diagnosis is proved and further studies are unnecessary. If there is no evidence of peripheral metastases, bronchoscopy should be the next procedure.

Bronchoscopy. Now that a greater number of cases of early bronchiogenic cancer are being discovered by chest roentgenograms, a revision of the present concept of the value of bronchoscopy as a diagnostic procedure is in order. The medical literature abounds with statistics indicating that 70 to 75 per cent of all bronchiogenic carcinomas originate in the major bronchi and are thus visible through the bronchoscope and accessible for biopsy.

These statistics are misleading in that they apply to all types of tumor without regard to time relations. They are false when applied to early carcinoma of the bronchus. As Gebauer² has shown, bronchoscopy if performed early yields negative results in 40 per cent of the cases because the site of origin is beyond bronchoscopic view. In addition to the time relation, the percentage of positive biopsies varies with the type of tumor. For instance, Gebauer demonstrated that 49 per cent of squamous-cell carcinomas originate in the upper lobes or small branch bronchi and that they are not likely to be accessible for biopsy until rather late in the disease. When one considers that epidermoid carcinoma is not only the most frequent but the most curable of all types of lung cancer, the significance of this finding can be realized.

Thus, the actual value of bronchoscopy in the early diagnosis of carcinoma of the lung can be stated in simple terms as follows. It still is the most valuable diagnostic procedure for securing tissue for biopsy. It is, however, an unreliable guide when the results are negative, since it does not in any way exclude the presence of a tumor immediately beyond the vision of the bronchoscopist. A negative bronchoscopy in a patient suspected of having pulmonary cancer thus means only that further diagnostic procedures are indicated. It cannot be emphasized too strongly, since it is a fact not generally recognized, that in the diagnosis of early cancer bronchoscopy is about 50 per cent inefficient.

Bronchography. If there is no evidence of peripheral metastasis and the bronchoscopy results are negative, the next step in the diagnostic procedure may be bronchography. At times, the instillation of lipiodol into the bronchial tree demonstrates

*All survey or single films that reveal abnormal shadows should be followed by a complete x-ray study of the chest. Fluoroscopy and multiple views that scan the lesion from various angles should be used. Lateral and oblique views are valuable for lobular localization. Often heavy-exposure (Bucky) films are necessary.

FIGURE 3 Case 2103

This 44-year-old man had complained of slight cough for several years, which was attributed to excessive smoking. In March, 1942, the sputum became blood-streaked. On the basis of the roentgenogram taken on March 18 (upper left), a diagnosis of pulmonary tuberculosis was made in spite of a persistently negative sputum. A roentgenogram taken two months later (upper right) showed progression of disease. The sputum was still negative, but the patient was still being treated for pulmonary tuberculosis. On the basis of a roentgenogram taken on July 28 (lower left), four months after the initial roentgenogram, a diagnosis of tumor was made. In the following month the patient was referred for surgical treatment. Bronchoscopy was negative. Nodes were palpable. A right upper lobectomy was performed. The patient made an uneventful recovery and remained well until December, when he developed evidences of metastatic disease, with death in February, 1943. The surgical specimen (lower right) was a Grade III epidermoid tumor with metastases to the bronchial lymph nodes. No mediastinal nodes were palpable. At the time of autopsy, metastases were found in the spleen, the left adrenal gland and the peritracheal and supraclavicular lymph nodes. Comment: This case demonstrates bronchiogenic carcinoma. It is early, stages. The persistently negative sputum with a changing x-ray lesion, would have misled the diagnosis and pneumonectomy would have offered a better chance of cure. Attention is called to the fact that bronchoscopy was negative even at the time of operation, when metastases had already occurred. This emphasizes the limitations of bronchoscopy in the early diagnosis of bronchiogenic carcinoma and the necessity for exploratory thoracotomy.

iently indicate an obstructive emphysema of bular, lobar or multilobar extent. More complete bronchial occlusion leads to atelectasis of similar segments of the lung. If this persists, superimposed infection of the involved parenchyma is the rule.

The x-ray manifestations depend on four factors — the type and location of the tumor, the degree of bronchial occlusion, whether infection of the parenchyma has occurred and whether mediastinal or chest wall extension has taken place. In the early stages, the most frequent x-ray findings are obstructive emphysema or atelectasis of lobular, lobar or multilobar extent. Less often, the tumor itself is seen — notably when it has originated in the periphery of the bronchial tree. Evidence of infection may be superimposed early. Extension to the mediastinum and chest wall, although certainly not a part of the early pathologic life of the tumor, sometimes occurs early in the clinical course.

From this incomplete consideration of bronchiogenic tumors, it can be seen that most of the symptoms usually listed as those produced by carcinoma of the lung, such as pain, excessive sputum, weight loss and cachexia, are as a rule not a part of the early picture. They are the result of extension of the tumor, secondary changes of lung parenchyma and the systemic reaction to both these processes. More frequently, the x-ray film shows definite changes, yet the symptoms are so mild as to cause little suspicion of such a serious underlying lesion. The latter type of case is the one oftenest seen in the early stages in survey work and clinical practice, and is the one on which we wish to focus attention. Most patients are men past middle age with a demonstrated x-ray lesion, accompanied by no symptoms or by mild ones. In many cases the only symptom is a mild cough, which is attributed to cigarette smoking. The clinical picture may mimic that of any of the ordinary diseases of the lungs. The x-ray manifestations may be indistinguishable from those of tuberculosis, bronchiectasis, unresolved pneumonia or suppurative disease. Such patients present a serious problem and one that demands immediate solution. If the lesion is caused by carcinoma, speed in diagnosis and surgical extirpation offer the only chance for cure. In no other disease process is time so dangerous an enemy. Early diagnosis and radical treatment in the early stage frequently lead to successful therapy. Without exception a policy of watchful waiting leads to ultimate death.

Thus, any patient, especially one past middle age, with persistent pulmonary symptoms or an unexplained x-ray lesion* should be immediately subjected to a series of diagnostic tests to prove or disprove the existence of cancer. Whenever

possible, tissue should be secured for pathological study, since this is the only sure way to establish the diagnosis.

Diagnostic Procedures

Search for peripheral metastasis. Careful examination of the cervical lymph nodes and the skin for evidence of metastasis should be made, and suspicious nodes or skin nodules should be removed for pathological study. If the biopsy is positive, the diagnosis is proved and further studies are unnecessary. If there is no evidence of peripheral metastases, bronchoscopy should be the next procedure.

Bronchoscopy. Now that a greater number of cases of early bronchiogenic cancer are being discovered by chest roentgenograms, a revision of the present concept of the value of bronchoscopy as a diagnostic procedure is in order. The medical literature abounds with statistics indicating that 70 to 75 per cent of all bronchiogenic carcinomas originate in the major bronchi and are thus visible through the bronchoscope and accessible for biopsy.

These statistics are misleading in that they apply to all types of tumor without regard to time relations. They are false when applied to early carcinoma of the bronchus. As Gebauer⁹ has shown, bronchoscopy if performed early yields negative results in 40 per cent of the cases because the site of origin is beyond bronchoscopic view. In addition to the time relation, the percentage of positive biopsies varies with the type of tumor. For instance, Gebauer demonstrated that 49 per cent of squamous-cell carcinomas originate in the upper lobes or small branch bronchi and that they are not likely to be accessible for biopsy until rather late in the disease. When one considers that epidermoid carcinoma is not only the most frequent but the most curable of all types of lung cancer, the significance of this finding can be realized.

Thus, the actual value of bronchoscopy in the early diagnosis of carcinoma of the lung can be stated in simple terms as follows. It still is the most valuable diagnostic procedure for securing tissue for biopsy. It is, however, an unreliable guide when the results are negative, since it does not in any way exclude the presence of a tumor immediately beyond the vision of the bronchoscopist. A negative bronchoscopy in a patient suspected of having pulmonary cancer thus means only that further diagnostic procedures are indicated. It cannot be emphasized too strongly, since it is a fact not generally recognized, that in the diagnosis of early cancer bronchoscopy is about 50 per cent inefficient.

Bronchography. If there is no evidence of peripheral metastasis and the bronchoscopy results are negative, the next step in the diagnostic procedure may be bronchography. At times, the instillation of lipiodol into the bronchial tree demonstrates

*All survey or single films that reveal abnormal shadows should be followed by a complete x-ray study of the chest. Fluoroscopy and multiple views that scan the lesion from various angles should be used. Lateral and oblique views are valuable for lobular localization. Often heavy-exposure (Bucky) is necessary.

a block in its secondary or finer divisions. Here again, it is important to realize that a negative bronchogram in no way rules out tumor. We

bronchoscopy is needed to obtain a biopsy specimen.

Study of sputum for malignant tissue. In the experience of most workers, and especially those

FIGURE 4 Case 1268

This 55-year-old man was first seen on November 24, 1940, at which time he had been under treatment for pulmonary tuberculosis for six months. His history revealed that six months previously he had had a "pneumonia" followed by a chronic cough and expectoration. In spite of a persistently negative sputum, a diagnosis of pulmonary tuberculosis was made, and the patient sent to a sanatorium, where he remained under treatment for six months. While there, his sputum was also negative on all tests. When first seen in November, his weight had dropped from 115 to 95 pounds. He complained of cough, expectoration of blood-streaked sputum, night sweats, and a dull pain in the right shoulder. Bronchoscopy revealed a mass protruding from the orifice of the right upper lobe, but biopsy of this revealed only necrotic tissue. Exploratory thoracotomy was performed. A large tumor was found in the right upper lobe. One mediastinal lymph node was enlarged, and frozen section of this revealed epidermoid carcinoma. A palliative pneumonectomy was performed. The patient did well for a few months and then rapidly became worse, dying in November, 1941. The roentgenogram taken just before operation (upper) suggests pulmonary tuberculosis, there being no indication of the large tumor mass found in the surgical specimen (lower). Comment: The chest roentgenogram in this case suggested pulmonary tuberculosis. The clinical course and the persistently negative sputum, however, should have indicated bronchoscopy and exploratory thoracotomy six months before the patient was referred for these procedures. It is possible that a curative type of pulmonary resection might have been performed at that time.

believe that bronchography should never be performed unless the results of bronchoscopy are negative because even if it demonstrates the tumor,

the average laboratory, the demonstration of cancerous tissue in the sputum has proved to be extremely disappointing. It is not recommended

a routine diagnostic procedure in cases suspected being cancer. If it is used it is of significance only when positive.

Aspiration biopsy. Aspiration biopsy is not without danger and should be used only in cases that are obviously inoperable, especially when the tumor is located peripherally. In cases considered operable, it seems to be unnecessary. A positive aspiration biopsy calls for surgical exploration to determine resectability. A negative one does not

diseuse for exploratory thoracotomy. For many years abdominal exploration has been an accepted procedure in establishing the diagnosis of unexplained tumor masses and lesions in the abdominal cavity. It is essential that physicians develop a similar attitude toward exploratory thoracotomy, if it is ever to be possible to treat a large proportion of cases of pulmonary cancer in the early stages. The value of this procedure can be gleaned from the fact that in 24 per cent of 153 cases reported

FIGURE 5 Case 3085

This 52-year-old man was first seen on June 17, 1944, at which time he complained of a slight cough and expectoration, after-riser fever and an intermittent dull pain just below the angle of the left scapula. A chest roentgenogram (upper) revealed an area of increased density at the left hilum and an infiltration in the left upper lobe. Bronchoscopy was negative. Bronchiogenic carcinoma was suspected and exploratory thoracotomy was about to be advised when the laboratory reported finding acid-fast bacilli in the sputum. The sputum was then cultured and a guinea pig inoculated. These proved to be negative. A chest roentgenogram taken just before operation (middle) showed slight clearing of the infiltration in the left upper lobe. Exploratory thoracotomy was performed on September 1 and a tumor was found in the left upper lobe near the hilum. There were also considerable induration and cupping of the lung tissue peripheral to the tumor. The surgical specimen (right) showed a large tumor (carcinoma unclassified) near the hilum as well as metastases to a bronchial lymph node. There was involvement of the parenchyma by infection distal to the tumor. Comment: This case illustrates several interesting points. First the symptoms were extremely mild. Second, the finding of acid-fast bacilli delayed exploratory thoracotomy, and if the laboratory report had been relied on the patient might have been subjected to treatment for pulmonary tuberculosis. Third, the chest roentgenogram gave little evidence of the presence of the tumor itself, in spite of its size. In this respect it resembles Case 1268. The findings in these two cases emphasize the limitations of a routine posteroanterior roentgenogram. Stereoscopic, lateral and even oblique views should supplement the posteroanterior film in all cases with pulmonary disease. Finally, exploratory thoracotomy was the only diagnostic procedure that could possibly have established the diagnosis.

rule out tumor, and therefore surgical exploration must be done to settle both the diagnosis and the question of operability.

Exploratory thoracotomy. Exploratory thoracotomy in suspected cases of tumor is a procedure that is used too little and too late. With the present-day status of thoracic surgery, this operation is on a par with abdominal exploration regarding safety and accuracy. In spite of this, there is still a great deal of hesitancy on the part of the average physician to refer a patient with unexplained pulmonary

by Overholt¹⁰ in 1942, the diagnosis was established and treatment was carried out on the basis of a biopsy specimen secured at exploratory thoracotomy. The sooner the pathologic process is discovered, the more valuable as a diagnostic procedure exploratory thoracotomy becomes. We believe that it should be carried out immediately to establish the diagnosis in all patients suspected of having pulmonary cancer, even though the bronchoscopy is negative, except of course, for those with proved metastasis. This concept is based on three es-

sentia facts First, it is a safe procedure. Second, it is an efficient procedure and establishes the diagnosis in the vast majority of cases when cancer exists Lastly, the diagnosis can be established at the operating table by frozen section, the operability determined, and the indicated operation carried out immediately

MEDIASTINAL TUMORS

The problem of mediastinal tumors is one of increasing importance, for mass surveys show that

The mediastinum is the site of many different types of primary tumor, because of the varied type of tissue present and the complexity of embryologic development of the contained organs From a pathological standpoint, mediastinal tumors present an extremely complex problem The clinical approach and treatment are, however, fairly well standardized

The problem with which we are now concerned is that of a patient whose mediastinal tumor has been discovered on the roentgenogram The

FIGURE 6 Case 2704

This 20-year-old man received a medical discharge from the Marine Corps because of a mediastinal tumor that had been discovered in routine x-ray examination He was in excellent health and entirely free of symptoms The preoperative roentgenogram (upper left) showed a large mediastinal tumor protruding to the right and left of the mediastinum Lateral views had shown that the tumor was in the anterior mediastinum A preoperative diagnosis of a teratoma was made The tumor was removed on December 9, 1943, the patient made an uneventful recovery and has remained well A chest roentgenogram taken ten months following operation (upper right) was essentially normal Examination of the surgical specimen (lower) proved the tumor to be an adenocystoma of respiratory epithelium Comment This case illustrates the size to which a mediastinal tumor can grow and cause absolutely no symptoms

they are much more frequent than has been suspected from previous clinical and autopsy data The incidence of mediastinal masses in a recent survey conducted by the United States Public Health Service¹¹ was 0.012 per cent Bloch and Tucker,¹² using routine fluoroscopic examination for all patients admitted to the University of Chicago clinics, found an incidence of mediastinal and diaphragmatic lesions of 0.57 per cent When the large number involved in such surveys is considered, the magnitude of the problem becomes evident

vast majority of those discovered in surveys cause either no symptoms or those so mild that they occasion little concern to the patient The physician must answer two questions what the nature of the mediastinal mass is, and how it is to be treated

Localization is of the utmost importance in determining the type of tumor The most frequent tumors of the posterior mediastinum are those arising from the sympathetic ganglions — ganglior neuromas — or the spinal nerves — neurofibromas The tumors oftenest found in the anterior medi

stinum are dermoid cysts, teratomas and malignant lymphomas, such as lymphosarcoma, Hodgkin's disease and leukemic lymphoma. It is therefore important to determine, if possible, whether the tumor is benign or malignant. The x-ray appearance helps to determine this. Benign tumors grow slowly and are usually oval or circular, quite dense, and sharply delimited laterally from the lung. Malignant tumors grow rapidly and are not so likely to be so smooth and discrete, but rather tend to be lobulated and less sharply defined from the

Treatment

Statistics and experience show that the vast majority of benign mediastinal tumors eventually cause death because of malignant degeneration, infection or mechanical pressure on vital structures in the mediastinum. It is generally agreed that surgical extirpation is the proper treatment. Successful removal is the rule. The mortality is extremely low, especially if the operation is performed when the tumor is small and before any secondary changes have occurred.

FIGURE 7 Case 3301

This 34-year-old married woman applied in October, 1942, for a position in a hospital where a pre-employment physical examination, including an x-ray film of the chest, is routinely required. The survey film (right) showed an area of increased density at the right base. Bronchoscopy was immediately performed, and an early primary adenocarcinoma of the right main-stem bronchus was found. Before the end of the same month that the survey film was taken, the chest was explored and an operable lesion was found. The surgical specimen (left) showed adenocarcinoma of right lower lobe bronchus, with indurative pneumonia distal to the occlusion. The lymph nodes were negative. Convalescence was satisfactory, and the patient has remained free of symptoms. Comment: This patient will probably be cured of a cancer for two reasons — first, because of the policy of one institution to require pre-employment chest x-ray films and, second, because of prompt investigation and treatment. If she had waited for symptoms to appear it might have been too late. If an explanation for the abnormal survey film had not been sought immediately it might have been too late. Fortunately for this patient the disease was apprehended when it was silent yet early, the potential danger of the lesion being fully appreciated.

pulmonary tissue. Cervical or axillary nodes are frequently associated with malignant lymphomas, and biopsy may prove the diagnosis. In case of doubt, a therapeutic test dose of x-ray helps to prove the nature of the tumor. Malignant lymphomas respond rapidly to x-ray therapy, whereas benign tumors are unaffected by it. In dermoids and teratomas, heavy-exposure roentgenograms with the Potter-Bucky diaphragm may reveal teeth or bone in the tumor. Fluoroscopy and roentgen-lymngraphy assist in ruling out aneurysm.

With these facts in mind, the treatment of mediastinal tumors can be expressed simply as follows. Surgical extirpation is indicated in benign tumors. An exception to this rule is a benign tumor in an elderly patient that is causing no symptoms. We advise frequent x-ray examination in such cases. So long as the tumor remains unchanged, no therapy is offered, but if it increases in size or causes symptoms, surgical removal is advised. In anterior mediastinal tumors, when there is doubt concerning the nature of the tumor, a therapeutic test dose

of x-ray is advised. If a response is noted, the tumor is considered to be a malignant lymphoma and x-ray therapy is continued. If the tumor fails to respond within four to six weeks, surgical exploration is advised. It is then important to proceed with excision without delay to avoid technical difficulties resulting from the effects of x-ray on local tissue.

SUMMARY AND CONCLUSIONS

Thousands of intrathoracic lesions are being discovered in mass x-ray surveys of the population. These patients are being referred to physicians in rapidly increasing numbers for evaluation and treatment.

Many lesions are in the early stage, when symptoms are either absent or so mild that the life-threatening lesion is unsuspected by both the patient and his physician. The immediate identification of the lesion and the institution of proper treatment during this stage offer the patient his best chance to get well. Delay may either rob him of an opportunity to have curative treatment or introduce factors that prolong or complicate such treatment. A significant proportion of all lesions discovered in survey work carry a definite threat to the patient's health and life.

A policy of watchful waiting until symptoms or extension forces the issue will not raise the percentage of salvages in either tuberculosis or cancer of the lung. The full value of survey work will not

be realized unless a proper disposition of all uncovered lesions is made.

The medical profession is faced not only with the obligation but also with the privilege of evaluating chest disease in advance of the time when most patients ask for help — after progressive disease has caused symptoms. The potentialities of this type of preventive medicine are great. The profession has within its grasp the power to overcome the plague of tuberculosis and to tear the label of certain death from cancer of the lung.

HOMOLOGOUS SERUM JAUNDICE FOLLOWING THE ADMINISTRATION OF COMMERCIAL POOLED PLASMA*

A Report of Eight Cases including One Fatality

CHARLES M. GROSSMAN, M.D.,† AND ERNEST W. SAWARD, M.D.‡

VANCOUVER, WASHINGTON

ALTHOUGH the occurrence of homologous serum jaundice has been repeatedly reported since 1937¹⁻¹⁴ the interest in this condition became widespread following its high incidence in American troops vaccinated against yellow fever in 1942.¹⁵ The reports of Beeson¹⁶ and others^{10, 17, 18} gave evidence of the occurrence of the disease following transfusion with whole blood or plasma. A recent report by Rappaport¹⁹ indicates that this sequela may not be infrequent in the armed forces. At present there are few reports of hepatitis in civilian hospitals following the administration of whole blood or plasma, although one might expect its occurrence to be frequent in view of the large amounts of plasma available for civilian distribution. In no reports have we seen any autopsy data although such information in cases of hepatitis due to homologous serum used with immunizing agents has been recorded.^{14, 20} The present report has been made to add to these data.

The discharge diagnoses of infectious hepatitis and catarrhal jaundice listed in the Northern Permanente Foundation Hospital files for September, 1943, to September, 1945, were reviewed with the object of separating all cases of homologous serum jaundice. Eight such cases appeared to satisfy the diagnostic criteria. One of these terminated fatally, and the autopsy findings are available for review.

It is recognized that any or all of these cases may represent a spontaneously occurring attack of infectious hepatitis. This criticism is, however, true of the other cases reported in the literature since there are no specific diagnostic criteria distinguishing these two conditions at the time when the hepatitis is present, the clinical and laboratory findings being identical. The etiologic agents of the conditions have many capabilities in common, such as those of passing through bacterial filters, of surviving temperatures as high as 56°C for a similar length of time and of being transmitted to new human hosts. Neither agent has successfully induced the disease in experimental animals, and the only known difference between them seems to be that relating to the incubation period. In homologous serum jaundice this is approximately fifty days to four months, whereas in infectious hepatitis

it is usually less than fifty days. Another possible difference is that of ease of transmission, since the former is apparently more difficult to transmit by the oral and nasopharyngeal routes than the latter.²¹⁻²⁴

CASE REPORTS

CASE 1 E. P., a 31-year-old state highway patrolman, was admitted to the Orthopedic Service on March 14, 1945, and was operated on the same day for a simple fracture of the femur with a Roger-Anderson pin fixation. He was given 250 cc of plasma on the day of operation. On May 26, after running an irregular low-grade fever for 12 days, he developed generalized aching pains, anorexia, nausea and vomiting. Jaundice was noted clinically for the first time on May 30, at which time the icteric index was 55. It rose to 70 on June 4 and fell to 14 on June 21. By June 16 the patient was asymptomatic except for the fracture.

CASE 2 A. S., a 62-year-old engineer, was admitted to the Orthopedic Service on October 19, 1943, for a compound fracture of the tibia. He was operated on with the Roger-Anderson pin technique, and on the same day was given 250 cc of plasma. He was discharged on November 6, but he was readmitted on January 22, 1944, with a history of epigastric distress, nausea and vomiting of 2 days' duration. The urine was dark and the stool was clay-colored. A tender liver edge was palpated on examination. The patient was obviously icteric, the index being 74. He was discharged asymptomatic on February 4, the icteric index having fallen to 41.

CASE 3 C. H., a 39-year-old rigger, was admitted to the Orthopedic Service on September 3, 1944, for a compound fracture of the left tibia and fibula. This was reduced by operation with the Roger-Anderson pin technique. On the day of admission he was given 250 cc of plasma. Manipulation of the fracture was done on September 25 and October 18. On October 20, anorexia developed. There was a brief episode of diarrhea at that time. On October 31, the icteric index was 26. By November 20, the icteric index was 84, but the patient was asymptomatic. By November 30, it had dropped to 25. There were no further symptoms.

CASE 4 M. N., a 27-year-old woman, a hospital employee, was admitted to the Gynecological Service on June 29, 1944, for perineal repair and a vaginal hysterectomy, at which time 250 cc of plasma was given. Recovery was uneventful. On October 15, the patient was admitted to the Medical Service because of jaundice. She gave a history of epigastric distress and abdominal discomfort since October 1, dark urine, first noted on October 3, and clay-colored stools on October 15. The icteric index on October 14 was 66. The patient improved on symptomatic therapy and was discharged on October 27. On November 10, the icteric index was still 18.

CASE 5 M. W., a 23-year-old woman, a painter's helper, was admitted to the Medical Service on June 4, 1944, in diabetic coma. As part of her therapy she received 250 cc of plasma. Recovery was uneventful and she was discharged but was readmitted on September 4 complaining of abdominal pain, diarrhea of 3 days' duration and nausea and vomiting for 1 day. She was obviously jaundiced, the icteric index being 50. She improved rapidly on symptomatic therapy. On September 18, the icteric index was 18.

*From the Medical Service of the Northern Permanente Foundation Hospital.

†Chief Medical Service, Southern Permanente Hospital, Fontana, California.

‡Chief Medical Service, Northern Permanente Foundation Hospital, Vancouver, Washington.

CASE 6 A B, a 39-year-old woman, a sheet metal worker, was admitted to the Medical Service on February 1, 1945, with lobar pneumonia and shock, for which she was given 250 cc of plasma. She was discharged asymptomatic on February 7, but was readmitted on March 26 complaining of nausea and anorexia of 1 week's duration. On March 26, the icteric index was 48, the stools were clay-colored, and there was some bile in the urine. On April 11, the icteric index rose to 110. By April 16, it was 28. The patient was asymptomatic at that time and was discharged.

CASE 7 T D, a 50-year-old shipwright, was admitted to the Medical Service on October 11, 1944, for pneumonia due to a Type 2 pneumococcus, with subsequent effusion. He had a history of duodenal ulcer. On October 11, he was given 250 cc of plasma. On October 27, he was discharged asymptomatic. On February 22, he was readmitted because of gastrointestinal symptoms, which were attributed to the duodenal ulcer, and a subtotal gastrectomy was contemplated. On March 5, however, the icteric index was 35. The jaundice increased, and since the question of obstruction of the common duct was raised, exploration was performed on March 12. At operation the liver was slightly enlarged, pale and brown, without evidence of a metastatic lesion. The stomach was normal except for a small, firm mass with some scarring on the anterior surface of the pylorus. The head of the pancreas was indurated, and there was considerable edema of the surrounding tissues. The gall bladder appeared slightly edematous. The common duct and cystic duct were normal. At the time of operation the surgeon was unable to explain the symptomatology, and in view of the jaundice a subtotal resection was not done. The icteric index rose to 90 on March 14 and then gradually subsided. Following the operation, the gastrointestinal symptoms subsided, and the patient was discharged improved.

CASE 8 I M, a 55-year-old sheet metal worker, was admitted to the Medical Service on March 13, 1945, for pneumonia of the right lower lobe due to Type 1 pneumococcus. He was given 250 cc of plasma, in addition to the usual chemotherapeutic and supportive measures. After a rather stormy course, he improved considerably and was well on discharge on April 8. He was readmitted on May 5 with acute tonsillitis and evidence of a recurrence of the lobar pneumonia, and was treated for 5 days, with a prompt response to penicillin therapy. He was again readmitted on June 5, 1945. At that time he stated that he had had a shaking chill, muscular pain, weakness and a nonproductive cough of 2 days' duration. The temperature was 103°F. Physical examination was essentially negative. The white-cell count was 4300, with 62 per cent neutrophils. The urine was normal except for a slight trace of albumin. On June 8, jaundice was first noted clinically. The icteric index was 70 on June 9 and rose to 90 on June 11. The prothrombin time on June 11 was 6 minutes (control, 30 seconds). The patient became irrational on June 10, and then comatose. He went progressively downhill and expired on June 12 in spite of supportive therapy.

Autopsy. The organs were deeply jaundiced, and numerous subpleural and subpericardial petechial hemorrhages were found. The liver was of normal shape but was somewhat decreased in size, measuring 20 by 20 by 5 cm. Its surface was smooth and dark in color. It was pliable and flaccid, but cut with increased resistance. On the cut surface was seen a distinct pattern of dark-red dots and small lines on a greenish-ochre background. Several large, edematous periportal nodes were found. The spleen measured 14 by 9 by 4 cm. The capsule was tense and pale gray. On the cut surface the splenic parenchyma appeared deep red and congested and was firm, and the trabecular pattern was prominent. Malpighian corpuscles were not seen. The gall bladder was normal and contained some dark-green bile. Its ducts were patent.

Microscopically, sections of the liver showed the capsule to be intact. In large areas no liver cells were found. Those that remained were either in the periportal areas or at the periphery of the liver lobules. In place of the liver cells only the somewhat dilated capillaries remained. Numerous large, pigment-laden macrophages were scattered throughout the liver, and there was infiltration with lymphocytes and plasma cells and occasional polymorphonuclear leukocytes throughout the sections. The periportal areas contained dense accumulations of lymphocytes. Several sublobular veins were found that exhibited marked phlebitis. Their walls were in-

filtrated with inflammatory cells, which pushed the endothelium into the vessel lumen, and small areas of necrosis were seen. The bile ducts in the periportal spaces were of normal appearance and showed no attempt at regeneration. The liver cells, when preserved, were finely vacuolated and were undergoing necrosis. Very rarely, large liver cells or those containing two nuclei were found. Sections of the spleen showed distinct malpighian corpuscles. The pulp was deeply hyperemic. Sections of the lymph nodes revealed that all sinusoids were markedly dilated and contained large amounts of lymphocytes, plasma cells and polymorphonuclear leukocytes. The reticulum cells were somewhat increased.

The final anatomical diagnoses were acute necrosis of the liver and congestion of the spleen.

All these patients had negative histories with regard to drug or alcohol ingestion and exposure to toxic substances. X-ray examination of the abdomen was negative in every case. No patient had evidences of anemia.

DISCUSSION

It will be observed that these patients had incubation periods ranging from fifty-four to one hundred and thirty-nine days, which conforms with the incubation period of the experimentally induced disease. It should be noted that the patients in Cases 1 and 3 were in the hospital throughout the time between the administration of plasma and the development of hepatitis.

In no case was there known occurrence of hepatitis in any of the members of the patient's family, nor was there any known contact incidence in the hospital. Among the 77 cases of infectious hepatitis studied at this hospital in the same two-year period, 13 (17 per cent) members of the patient's family had or subsequently developed jaundice.

None of the patients were seriously ill except the one in Case 8. The autopsy findings in this case differed in no way from those in cases ending in death following hepatitis due to the administration of yellow-fever vaccine,^{14 20} nor are the findings different from those in deaths from infectious hepatitis.²⁸ In the absence of a biopsy, the operative report in Case 7 supplied no significant information, although the findings are not without interest.

During the two-year period during which these cases were observed, five hundred and one transfusions of commercial pooled plasma were administered. The plasma was purchased from a commercial manufacturer with nationwide distribution facilities, who states that each pool consists of at least fifty samples. The occurrence of 8 cases gives an incidence of 2 per cent, but this represents a minimal rather than a true incidence, since many patients received more than one transfusion and since patients who developed hepatitis were treated as outpatients or by physicians elsewhere did not come to our attention. Furthermore, patients who did not develop clinical jaundice but nevertheless had the clinical features of acute hepatitis, such as nausea, vomiting, anorexia and malaise, were not included. For example, we observed one patient with these symptoms and an icteric index of 15

ninety days after a transfusion of whole blood whose case suggests this possibility. Rappaport¹⁹ has included 2 such cases in his report.

The true incidence of this condition is not known at the present time. Reports in the literature vary from as many as 26 of 47 cases receiving pooled serum in one instance¹³ to ten thousand transfusions of pooled plasma without any recorded evidence of homologous serum jaundice,²⁶ although in the latter report the authors state that their method may not have supplied complete data. The reasons for this discrepancy are manifold. Since there is a relatively high incidence of infectious hepatitis at the present time, it is only natural to attribute any example of this clinical picture to spontaneously occurring agents. The long incubation period of homologous serum jaundice separates the disease from the etiologic event by such a long period that causal relation may be overlooked. Finally many physicians may not be alert to this possibility because of the absence of information about this condition in the literature until the last few years.

The incidence of this disease is undoubtedly becoming greater because of the increased use of commercially pooled plasma in cases in which transfusion of whole blood from a single donor was formerly used. Our experience has confirmed this since nearly one thousand whole-blood transfusions were given at this hospital in the same two-year period with no case of manifest jaundice. The chance of the etiologic agent's being given in any blood plasma therapy is many times increased as pools of fifty or more donors are mixed. The amount of icterogenic plasma necessary to contaminate a pool is minimal, since the disease can be transmitted by as little as 0.1 cc.^{13, 21, 22}

In view of the disability²⁷ and the chance of fatality in homologous serum jaundice, the use of pooled plasma is not without danger. The fact that the icterogenic agent is not destroyed by drying and prolonged storage²³ makes the tracing of the icterogenic sample difficult. Since it has been reported that the agent is destroyed by ultraviolet radiation,²¹ perhaps the hazard from the use of pooled plasma could be obviated by such a method.

SUMMARY

Eight cases of hepatitis with jaundice following the use of commercial pooled plasma are presented, 1 of these being a fatal case, with autopsy data available.

The factors relating to the apparent incidence are briefly reviewed.

It is suggested that the hazard of hepatitis and even fatality from pooled plasma is greater than that of a whole-blood transfusion from a single donor.

TYPHOID-BACILLUS INFECTION OF A SURGICAL WOUND TREATMENT WITH A URETHANE-SULFANILAMIDE MIXTURE*

Report of a Case

LOUIS WEINSTEIN, M D †

BOSTON

ALTHOUGH the occurrence of localized areas of suppuration caused by the typhoid bacillus is on the whole infrequent, McCrae¹ believes that during typhoid fever no part of the body in which abscesses may occur is exempt. *Eberthella typhosa* and pyogenic cocci, acting either alone or in combination, are the usual etiologic agents in this type of complication, which may occur without any apparent inciting cause, or as the result of injury to tissue by needle punctures, spontaneous hematomas or surgical procedures.

In most cases of abscess appearing in the course of typhoid fever, the lesions appear in various tissues without any apparent inciting cause. The buttocks are the most frequent site of abscess formation (McCrae¹). Although localized areas of suppuration in the viscera are rare, spontaneously occurring abscesses of the thyroid gland, the cervical lymph nodes, the submaxillary glands, the breast (Sappington²), the spleen (Ransohoff and O'Rourke³), the ovary (Widal and Ravaut⁴), the rectus sheath (Bullowa⁵), the thigh muscles (Vires, Mas and Serre⁶), the muscles at the lower end of the sternum (Gannon⁷) and the peritoneal cavity, with or without perforation of the bowel, have been described. The reason for the focalization of typhoid bacilli in these various organs in typhoid fever in a particular patient is not apparent, but it seems most probable that during the stage of bacteremia organisms become located in these sites and, having established themselves, produce destruction of tissue.

Parenteral administration of various drugs has been incriminated in a number of cases as the cause for localization of typhoid bacilli in various muscles that have been used as sites of injection. Achard and Weil⁸ have reported a case of abscess formation in muscle seven days after an injection of methylene blue in a patient with typhoid fever, aspirated pus yielded *E typhosa* in pure culture. The intramuscular or subcutaneous administration of quinine (Schneider⁹), caffeine (Widal and Le Sourd¹⁰ and Malenchini and Pieraccini¹¹), oil of turpentine (Rathery and Bonnard¹²) and camphor (Tobias and D'Estefano¹³) has been reported as leading to formation of abscesses in some patients with typhoid fever, in most cases, the enteric organism causing

the primary disease was isolated in pure culture from the localized area of suppuration. Tobias,¹⁴ who has recorded 2 cases of abscess formation due to the typhoid bacillus in typhoid-fever patients to whom camphor was administered parenterally, has expressed the opinion that such lesions when occurring during the acute course or convalescence of enteric fever are practically always due to *E typhosa*. The pathogenesis of suppuration of this type appears to be mechanical irritation by the injected drug, with production of an area of decreased resistance and subsequent localization of organisms. Tobias could find no indication from his own cases or those reported in the literature that the appearance of an abscess has an unfavorable effect on typhoid fever, as a matter of fact, he expressed the opinion that in some cases the course of enteric fever is beneficially influenced by the development of a localized area of suppuration. Local injuries occurring without injections, such as hematomas in muscles, — which may result either from Zenker degeneration, which is sometimes present in typhoid fever, or from prolonged vomiting and coughing, affecting the abdominal muscles, — may serve to produce areas that are particularly susceptible to the establishment of the typhoid bacillus.

In spite of the fact that a moderate number of patients with typhoid fever develop complications requiring operative intervention, such as incision and drainage for osteomyelitis or laparotomy for intestinal hemorrhage or perforation, and that *E typhosa* is capable of producing localized areas of infection, there is a scarcity of reports concerning suppurative complications of surgical wounds, a search of the literature having revealed only 2 such cases. Rathery and Bonnard¹² have described a case in which, following appendectomy because of pain in the right lower quadrant occurring at the onset of typhoid fever, the patient developed a superficial infection at the lower end of the operative wound, which, when incised and drained, yielded a pure culture of *E typhosa*. A similar case of wound infection due to the typhoid bacillus following removal of the appendix in a patient who subsequently developed typhoid fever has been reported by Marta.¹⁵

The purpose of reporting the following case is to describe typhoid-bacillus infection in a surgical wound in the leg, without underlying osteomyelitis or periostitis, in a patient in whom the diagnosis

*From the Haynes and Evans Memorials, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine.

This study was made with the aid of a grant from the Johnson Research Foundation, New Brunswick, New Jersey.

†Assistant professor of medicine, Boston University School of Medicine; visiting physician, Haynes Memorial, Massachusetts Memorial Hospitals.

f typhoid fever was first suspected on the basis of the bacteriologic findings in the local lesion, to point out the possible role of localized areas of suppuration in the spread of typhoid fever if, owing to lack of an exact bacteriologic diagnosis, proper precautionary measures are not taken, and to demonstrate the highly effective action of a mixture of urethane and sulfanilamide in the eradication of *E. typhosa* from a suppurated wound.

M.C., a 68-year-old married woman, was transferred to the Haynes Memorial Hospital from the Orthopedic Service of the Massachusetts Memorial Hospitals to which she had been admitted on November 10, 1944, because of a fracture of the right femur sustained in a fall. She had enjoyed fairly good health until 3 weeks before admission to the Massachusetts Memorial Hospitals at which time she had a mild febrile illness characterized by generalized aching and a low degree of fever. A physician made a diagnosis of an upper respiratory infection and recommended bed rest for several days. Recovery occurred without any further treatment and the patient remained well until the fall which resulted in an intratrochanteric fracture of the right femur.

Open reduction was carried out on the day of admission and the bone ends were approximated by means of a Blount plate with complete closure of the wound. The course was uneventful until the 10th postoperative day, when there was a moderate elevation of temperature and the wound in the thigh appeared reddened, swollen and boggy and began to discharge purulent exudate. Cultures of the pus revealed *E. typhosa*. A macroscopic Widal test gave a positive reaction in a serum dilution of 1:320; both the organism isolated from the wound and a laboratory strain of the typhoid bacillus being used as antigens. Two subsequent cultures of the exudate from the wound taken during the next several days revealed the same organism. Because of these findings the patient was transferred to the Haynes Memorial Hospital on December 6 for further care and treatment.

At physical examination on admission the temperature was 104°F, the pulse 90, the respirations 20, and the blood pressure 125/75. The patient appeared much older than her stated age. She was moderately well developed and poorly nourished, appeared chronically ill and was unable to give an adequate history because of an extremely poor memory. There were no rose spots or petechiae or a rash of any kind on the skin. The mucous membranes were pale and moist and showed no abnormal pigmentation or hemorrhagic areas. The posterior cervical and axillary lymph nodes were palpable, small, of normal consistence and non-tender. There was no other lymphadenopathy. The pupils were equal in size and round and reacted to light and on accommodation. The scleras and conjunctivas were clear and of normal color. Examination of the eyegrounds revealed the disks to be of normal color, the margins well outlined and cupping of a normal degree. The retinal vessels showed narrowing, tortuosity and a moderate degree of arteriovenous nicking. No exudates or hemorrhages were seen. The right ear drum showed an old perforation, and the hearing was poor. The pharynx was clear and of normal color. The mouth showed no abnormalities except for absence of all but seven teeth, which were in poor condition. There was slight atrophy of the papillae of the tongue. The neck was not stiff, and there was no engorgement of the veins. The trachea was in the midline. The thyroid gland was not palpable. Examination of the chest revealed an increase in the anteroposterior diameter and equal expansion on both sides. Percussion over both lung fields was hyper-resonant, tactile and vocal fremitus were within normal limits and the breath sounds were clear except for a few dry rales at the right base. Examination of the heart revealed a diffuse impulse in the 5th left interspace at the midclavicular line, a regular rhythm, distant sounds and a rate of 90 per minute. There was a Grade II rough blowing systolic murmur heard best over the aortic area and transmitted down over the precordium. The pulmonic second sound was greater than the aortic.

The abdomen revealed no spasm, masses or tenderness. The liver was palpable 2 or 3 fingerbreadths below the right costal margin. The spleen and kidneys were not palpable.

No petechiae were noted on the abdominal wall. The genitalia were atrophic but revealed no other abnormalities. Examination of the extremities showed a well healed longitudinal scar 20 cm. in length on the lateral aspect of the right hip, in the center of this was a small sinus 1 cm. in depth from which drained a small amount of thin, grayish, foul-smelling exudate. Palpation of the scar revealed no tenderness or masses. The extremities were otherwise normal except for moderate pitting edema of both ankles. Neurologic examination showed the deep and superficial reflexes to be physiologic. No abnormal reflexes could be demonstrated.

A specimen of urine taken on admission had a specific gravity of 1.014 and contained no albumin, sugar or abnormal cellular elements. During the hospital stay, the specific gravity varied from 1.009 to 1.032, the albumin from 0 to ++, on one occasion and sugar was always absent. There were two episodes of pyuria, one in the 3rd and the other in the 7th week of the illness.

The red-cell count and hemoglobin were 3,910,000 and 10 gm. respectively, and remained at about these values during the hospital stay. The white-cell count was 6650 with 86 per cent neutrophils, 13 per cent lymphocytes, and 1 per cent eosinophils, and fluctuated thereafter between 4000 and 16,600 with essentially normal differential counts except on one occasion during the 2nd week, when 9 per cent eosinophils were present. The nonprotein nitrogen varied between 24 and 30 mg. per 100 cc. The serum calcium was 10.35 me. per 100 cc. and the phosphorus 4.5 mg. The alkaline phosphatase level of the blood was 6 King-Armstrong units per 100 cc.

Cultures of the draining sinus in the right thigh made on admission revealed *E. typhosa* and a hemolytic *Staphylococcus aureus*. The gram-negative organism was again recovered 2 days later, but thereafter daily cultures of the wound, so long as it persisted, never again revealed the typhoid bacillus. On the 47th hospital day, 11 days after removal of the Blount plate, purulent exudate reappeared in the wound and bacteriologic studies revealed *Pseudomonas pyocyanica* in pure culture. This organism disappeared after 3 days of treatment. Further wound cultures were sterile.

Several cultures of the stool during the first 2 weeks in the hospital were negative for the typhoid bacillus, but in the 3rd week it was isolated. Five stool cultures made during the remaining 6 weeks were all positive for *E. typhosa*. Agglutinins against the typhoid bacillus, which had been present in a serum dilution of 1:320 on admission, rapidly increased, so that at the end of 2½ weeks they were detectable in a 1:1280 dilution.

X-ray examination of the chest revealed a few calcified mediastinal nodes and a network of increased density in both lungs, more marked on the right than on the left. There was no evidence of metastatic or primary neoplastic pulmonary disease. The right humerus showed an area of rarefaction made up of more or less round, pitlike areas measuring from 5 to 10 mm. in diameter, with sharply defined borders. Above this area was an amorphous calcification in the greater tuberosity. These findings were considered consistent with a small area of aseptic necrosis and were not thought to indicate neoplastic disease of the bone. Three roentgenologic examinations of the right femur at different times during the illness revealed no evidence of periostitis or osteomyelitis.

The temperature remained normal during the first 3 days in the hospital, fluctuated between 99 and 101°F for the next week and gradually declined to within normal limits for the remainder of the hospital stay.

The volume of the sinus in the right thigh, as determined by the injection of sterile saline solution, was about 30 cc. After the causative agent of the infection in the operative wound had been identified, injection of 15 cc. of a sterile aqueous solution of 10 per cent urethane and 1 per cent sulfanilamide¹⁵ into the sinus every 4 hours throughout the day and night was begun. Under this regimen cultures of the wound for *E. typhosa* became negative in 36 hours and remained so during the remainder of the period of observation. The cavity decreased rapidly in size so that it was completely closed in 15 days. The quantity of urethane-sulfanilamide mixture injected daily was gradually diminished as the size of the sinus tract decreased, and treatment was stopped after 12 days.

On the 12th hospital day the patient complained of a sudden attack of intense, knifelike pain in the right hip, which was relieved by rest but markedly aggravated by even slight

motion of the leg. Examination revealed an area of tenderness on the lateral aspect of the right hip. Lateral rotation or flexion of the right hip joint produced severe pain. There was no change in the appearance of the wound, no masses or tenderness could be elicited, and no exudate was present. The temperature and white-cell count were within normal limits. Morphine sulfate was administered and sandbags were applied to the leg to immobilize it. X-ray examination of the right femur revealed penetration of the head of the femur by the blade of the Blount plate, the point of which was lying in the joint space. Subsequent treatment by the application of Buck's extension and sedation produced complete relief of pain in 3 days. Twenty-four days later, the healed wound in the leg was reopened and the plate was removed. At operation, the bone was found to be completely united, the muscles and fasciae were in good condition, and nowhere was there any evidence of infection. Cultures taken from various sites in the operated area were sterile.

On the 11th day after operation, the wound opened spontaneously and discharged purulent exudate, from which *Ps. pyocyanea* was obtained in pure culture. The urethane-sulfanilamide mixture was applied every 4 hours to sterile dressings packed into the wound, and within 3 days the pigment-producing organism was absent, the purulent discharge ceased, and healing progressed so rapidly that the wound was completely closed 10 days after treatment was begun.

The hospital course was complicated by two episodes of pyuria, one in the 2nd hospital week and the other in the 7th. Bacteriologic study of the urine during the first bout revealed a pure culture of *E. typhosa*. Several subsequent urine cultures were sterile until the second attack of pyuria, at which time a pure culture of *Ps. pyocyanea* was isolated. Treatment with 2 gm. of sulfathiazole a day produced clearing of the urine in a short time.

Since the patient had become a typhoid carrier and required constant nursing attention because of her poor mental status, she was transferred to another hospital.

DISCUSSION

There are several aspects of this case that merit detailed discussion. The original illness three weeks before fracture of the femur was in all probability an episode of extremely mild typhoid fever, which at its inception was mistaken for an upper respiratory infection, no effort being made to isolate the patient. Although the presence of *E. typhosa* in the urine and stool could well have been due to the carrier state, the rapidly rising agglutinin titer indicates active infection. Had the patient not incurred a fracture of the hip, with subsequent infection of the operative wound by the typhoid bacillus, the diagnosis of typhoid fever would in all probability never have been made.

The manner in which the enteric pathogenic bacteria gained entrance to the wound is open to conjecture. It seems probable that the organisms were not brought to the site of operation by the blood stream, since, if it is assumed that the original illness three weeks previously was typhoid fever, the bacteremic stage should have been over for an appreciable time. In the third week of typhoid fever, it is usual to find the organisms either in the stool or the urine or in both, and it seems most probable that the wound infection took place as a result of the introduction of organisms during or after operation through the skin of the thigh, which was contaminated either with fecal material or with urine. That the organisms did not enter the wound as a result of infection of the under-

lying bone or periosteum seems likely, since no roentgenographic evidence of osteomyelitis or periostitis was obtained. That there was a typhoid bacillus abscess in the thigh muscles that was entered at the time of operation seems unlikely, since suppuration did not appear in the wound until ten days after surgical intervention. A remote possibility is that the organisms were present in the bone marrow without producing signs of osteomyelitis and were introduced into the wound during the procedure of inserting the Blount plate.

The similarity of the urine and wound culture during the episodes of pyuria is of interest. When the wound was infected with *E. typhosa*, the same organism was isolated in the urine culture, and since there was marked pyuria, it seems proper to assume that the patient at that time had an acute pyelonephritis due to the typhoid bacillus. When, following the second operation, the wound became infected with *Ps. pyocyanea* and pyuria recurred, this organism was also cultured from the urine. These findings add some evidence in support of the possibility that infection of the wound resulted from contamination with bacteria that were present in the urine or the stool.

It has previously been demonstrated that *E. typhosa* is extremely susceptible to the action of urethane, large numbers of these bacteria being killed in the test tube by an exposure of five to ten minutes to a 10 per cent concentration of this drug in broth.¹⁶ The bactericidal effect also appears to be exerted in vivo, since treatment of the wound described above with a mixture of 10 per cent urethane and 1 per cent sulfanilamide resulted in complete sterilization within thirty-six hours. *Ps. pyocyanea* has also been found to be highly susceptible to the action of urethane in vitro,¹⁶ and this effect is apparently unaltered by the presence of a tissue or exudate. This drug seems worthy of a trial in any localized infection with the typhoid bacillus, *Ps. pyocyanea* or other gram-negative organisms. It seems unlikely that the sulfanilamide in the mixture had any appreciable effect, since it is well recognized that the sulfonamides are relatively inefficient against gram-negative bacilli.

The danger of failure to recognize the presence of the typhoid bacillus in localized areas of suppuration should be stressed. If the diagnosis of typhoid fever is missed, as it may well be in extremely mild cases, such infected areas, which may be discharging a purulent exudate laden with *E. typhosa*, may be responsible for the transmission of the disease to other persons because of lack of proper precautionary measures. As a matter of fact, a patient who was in the ward at the same time as the one described above became ill with severe typhoid fever and, so far as could be ascertained, the case reported was the source of the infection. Rubenstein^{17, 18} has stressed the importance of unrecognized typhoid bacillus infection

n patients with acute or chronic cholecystitis who undergo surgical treatment as a source of spread of typhoid fever

The possibility that wounds occurring during the course of typhoid fever, either accidentally or as the result of various therapeutic procedures, will become infected with the typhoid bacillus must always be kept in mind by those treating this disease. The possibility that these secondary lesions will act as sources for the spread of infection to susceptible persons must be carefully considered in the establishment of proper isolation technic. The rarity of reports of secondary infections of wounds with *E. typhosa* in patients who are operated on for the intestinal complications of typhoid fever is quite surprising, and it must be assumed that, on the whole, the resistance of skin and muscle to infection by the typhoid bacillus is high. A careful bacteriologic examination of all local areas of suppuration occurring in the course of typhoid fever is imperative.

SUMMARY

A case of infection of a surgical wound with *Eberthella typhosa* in a patient who probably had an undetected mild attack of typhoid fever several weeks prior to operation for the open reduction of a fracture of the femur is described.

Treatment of the local infection with a solution containing 10 per cent urethane and 1 per cent sulfanilamide led to rapid eradication of the infecting bacteria and healing of the wound.

The importance of localized areas of suppuration due to *E. typhosa* cannot be overemphasized because, unless promptly recognized bacteriologically and the necessary precautions taken, spread of typhoid fever may occur.

SYMPOSIUM ON MEDICAL SOCIOLOGY

MEDICAL PRACTICE AND ITS FUTURE*

LELAND S. MCKITTRICK, M.D.†

I UNDERSTAND that my place in this symposium is to tell you something of medical practice as it is today and something of its past, and to speak of those forces within and outside of medicine whose influences point toward the medical practice of tomorrow.

You are approaching the end of your medical-school training. Except for minor digressions, your thoughts and efforts have been on the scientific aspect of your chosen profession. What you may know of the actual practice of this profession cannot have come from personal experience.

Clinical medicine is not a science. It is the utilization of what we have learned from study and experience to determine and interpret the variable physiologic and anatomic responses of the body and mind to external or internal stimuli, and the application of this knowledge in such a manner that the proper treatment will be prescribed and will be accepted and carried out by the patient and his family.

THE DOCTOR

The practicing physician is the infantryman of the medical profession. To understand the practice of medicine, one must understand him, and this is not easy — especially for the nonprofessional person.

What are some of the outstanding characteristics of a good physician? A well developed intellectual curiosity, complete honesty, both moral and intellectual, and a devotion to his work that makes him available at all times of every day are some of the qualities that you have a right to expect in your doctor.

What are the factors that tend to develop and maintain in the physician the qualities that are so essential to good medical care of a community? I am not at all sure that I know the whole answer, but I believe that I do know at least a part of it. There are well recognized minimal requirements that medical schools must fulfill to give their students the minimum training essential to an adequate background for the practice of medicine. Schools that do not fulfill these requirements but accept medical students for training are of themselves inherently dishonest, and therefore cannot be ex-

pected to develop honesty in their students. A good school, a careful selection of students and the elimination of these found to be intellectually or morally unfit are, then, the first essentials.

The development of the proper emotional background of the doctor extends over a period of many years. Stimulated in the medical school, the young doctor has his most intensive exposure to the professional mind during his internship and in his association with the older men in the earlier stages of his entry into the actual practice of medicine. The practice in our teaching hospitals of holding staff meetings in which deaths, complications and errors are openly and frankly discussed exposes the young mind to a form of intellectual honesty not previously encountered. I thrill with pride each time one of our hospital residents voluntarily presents before the medical students and the staff a patient in whose management he has erred. By this action, he has accepted one of the basic principles of intellectual honesty, he has kept faith with himself, and has done what he could to prevent others from committing the same mistake.

Competition, both economic and professional, is an important and a most powerful influence. The practice of medicine to most doctors is their chosen way of making a living, and conversely, most doctors are dependent on their professional income for a livelihood. Every doctor knows that a satisfied and grateful patient is his greatest asset. You are rightfully told that if you can be a better doctor than your neighbor, are honest in your dealings with patients and are solicitous of their best interests, mentally and physically, you can be assured of a loyal and increasing group of patients and of satisfactory financial returns.

Every physician knows only too well of the patient's inability to distinguish what is good in medicine or surgery from what is bad. He knows, too, that there is no legislation or regulation that can adequately control the quality of medical or surgical care, except such regulations as are made by his professional associates. As a doctor, then, he not only has to satisfy the demands of his patients, but he must constantly strive to avoid any action that may receive the criticism of those professional associates, young or old, whose judgments he respects.

We hear much of the stimulus to do better work because of the personal relation between the doctor and the patient, and of the importance of the free

*This is the sixth of a series of nine lectures on medical sociology given weekly at Harvard Medical School during January, February and March 1945. They were sponsored by the Department of Preventive Medicine and were primarily intended for third year students. These articles will temporarily replace the reports "Medical Progress."

†Associate in surgery, Harvard Medical School, visiting surgeon, Massachusetts General Hospital.

choice of a physician. There are many variations in the quality of medical care, not only within the same wards of our hospitals but even among patients under the care of a given member of the staff. We might not like to admit this, but if we are honest with ourselves, we shall realize that we are emotional human beings and that we respond to certain stimuli, just as do others who are differently trained. Later on in your daily work you will see patients under varying conditions — patients in the hospital wards who are merely the hosts of a given disease, the patient who may be referred to, not as Mrs. Jones, but "the woman in the corner bed with a cancer of the stomach." You will treat that patient's disease well. Later in the day you may go to your office and see a young mother with a similar condition. She tells you frankly that you operated on a relative or a friend of hers and that her doctor suggested the names of several surgeons, but that she came to you because she knew of you and wanted you to operate on her if an operation was necessary. She expresses her confidence in you and her willingness to do whatever you advise, whenever you say it should be done, and she may well add, "I want to put myself completely in your hands." The quality of medical care that a given patient will receive from you as a doctor is dependent not only on your ability and experience but on the intensity with which you apply yourself to a given problem, and not infrequently it is this effort, over and above the average, that means the difference between life and death to the patient. Theoretically, all patients should get from the same doctor the same detailed care. Nevertheless, rightly or wrongly, the man who comes to you because he believes in you over and above anyone else is the patient who may well get from you that extra effort that represents the difference between the best you have to offer and just good medicine.

You may well feel that I have given too much time to the role of the individual, but the medical service of any community can be only so good as the doctors who are giving it. In any plan or discussion, therefore, that involves the relation between the doctor and society, there must be included a discussion of the quality of the service that is to be given, as well as the factors that influence its availability or its extension.

THE STRUCTURE OF MEDICAL PRACTICE

Various possibilities await the young man who has had a good training in his chosen branch of medicine. Time will only permit a limited discussion of the more significant of these.

A relatively small group of extra able, intense young men, whose great interest is in the teaching and advancement of the science of medicine rather than in the care of the patient, will go directly into full-time positions in large teaching hospitals. They will become the outstanding leaders in the medical

education of tomorrow. On their shoulders will fall the responsibility for the scientific advancement of medicine and that of pointing the way to its clinical application. The importance and responsibilities of the subclinical branches of medicine, such as bacteriology, pathology and radiology, are now well recognized and attract an increasing number of young graduates. The great majority of young men and women, however, will go into clinical medicine, and for them there are a variety of opportunities. Many will return to their own homes or will go to their chosen communities as assistants to experienced and successful practitioners. This association is particularly valuable to the young surgeon.

Affiliation with an organized group, contract work in industry or simply starting a solo practice from scratch are some of the more usual openings. However interesting and instructive these first years may be, with but few exceptions they will not be productive from the financial point of view. They are considered to have been well spent if they permit a scant living but permit a continued opportunity to learn and to become acquainted in the community in which one expects to continue practice.

Probably the most difficult problem faces the young surgeon. In recent years it has been quite generally accepted that a minimum of five years after graduation is necessary for his training. By the end of this period he will have had an intensive exposure to surgical problems and will have become accomplished, although still relatively inexperienced in the performance of surgical operations and in the care of surgical patients. The surgeon's confidence in himself, his ability to make decisions, and his technical skill, are rapidly lost, however, unless he can maintain a constant exposure to the problems of surgery and their solution.

Patients and referring physicians are slow in putting their confidence in a young surgeon, even though well trained. Moreover, the latter himself soon finds that whereas he has had an excellent training in the running of a surgical service and in the technical aspects of surgery, there are many practical problems involved in obtaining and maintaining the confidence of the patient, his family and the local physician that can be mastered only through experience under the conditions associated with the actual practice of surgery.

During this transition period, how is the young surgeon to maintain his technical skill while he acquires these other essentials necessary to his success? This question is immediately answered for those fortunate enough to obtain an association with a successful, experienced surgeon or with a group of surgeons, but for those not so fortunate this represents one of the major problems facing postwar medicine, and the answer is not yet at hand.

In summary, American medicine of today consists of fulltime research workers and teaching physicians, the fee-for-service doctors, the organized

clinics, either under the fee-for-service system, best exemplified by the Mayo, Crile and Lahey clinics, or the contract-service system, as offered by the Ross-Loos Clinic, of Los Angeles, and contract work, including insurance practice, such as has been in force in many parts of this country for the past half-century. In addition there are the subclinical branches of medicine so essential to modern practice.

INFLUENCES WITHIN THE MEDICAL PROFESSION

Time will only permit the consideration of some of the more important forces within the profession that have influenced or are influencing medical practice in this country.

The American Medical Association

The American Medical Association was founded in 1847 "to promote the science and art of medicine and the betterment of public health." The *Journal of the American Medical Association* appeared in 1881, but neither it nor the Association was an active power in American medicine until the early part of the twentieth century. Membership is open to all legally registered physicians or graduates of qualified medical schools who have fulfilled the requirements of the local county medical society, in other words, membership in the latter automatically gives membership in the state and national organizations, with no additional dues or assessments for the latter. Members who subscribe to the official journal or one of its specialty journals become fellows of the Association. About 125,000 (approximately 70 per cent) of the physicians of this country are now members of the American Medical Association.

Although primarily educational in scope, the Association has a profound influence on medical practice. In recent years it has been much criticized for its conservatism, as expressed by its opposition to radical changes in the methods of medical practice. Although there is ample evidence that it has accepted certain changes, it is difficult to find anything to suggest an aggressive attitude on the part of the Association in favor of such changes, and it has violently opposed any alterations that are considered detrimental to the welfare of patients. There is, however, in the literature overwhelming evidence of its contribution to the advancement of the quality of medical education and medical care in this country. Only the briefest reference may be made to the more significant of these contributions.

In the early nineteen hundreds, through its Council on Medical Education and Hospitals, the Association was the most important single factor in setting and obtaining acceptance of the minimum standards of medical education and in eliminating a large number of so-called "diploma mills" and substandard medical schools. As a result of this, the number of medical schools in this country was

reduced from one hundred and sixty-six to seventy-seven.

The American Medical Association is the central figure in the most comprehensive and effective system known for the perpetuation and exchange of medical information and opinion. The *Journal of the American Medical Association* is probably the foremost medical journal of the world. In addition, the Association has created and supports journals in many of the specialties, as well as the *Quartiers Cumulative Index* and *Hygieia*, a magazine to the laity.

The educational value of the annual meeting of the Association, with its scientific exhibit, is outstanding. The councils on Pharmacy and Chemistry, Foods and Nutrition, and Physical Medicine and the many committees appointed from time to time, such as the Committee on Cosmetics, the Committee on Contraceptives, the Committee on American Health Resorts and various committees appointed by sections, have helped to correlate scientific knowledge and to promote rational thinking in their respective fields, as well as to demonstrate that honest advertising is not only a moral obligation but is also consistent with profitable and satisfying material progress.

The Association's relentless campaign against quackery is well known. According to *Fortune*, this has resulted in the American Medical Association's being threatened with suits totaling \$35,000,000 in the thirty years prior to 1938, of which only two ever came to trial, the total assessed damages amounting to just one cent.

It has fully co-operated with our government in the prosecution of the war, and is at present taking a leading part in plans for the guidance and post graduate education of returning medical officers after the war.

Group Clinics

Fee-for-service system. The late nineties and the early nineteen hundreds saw in Rochester, Minnesota, the beginning of what was to become the best known group clinic in the world. As the years passed, the Mayo Clinic, under the guidance of Dr. Will and Dr. Charles, became the center of the best in medicine and surgery, and one of the best in scientific research and the training of physicians. Subsequent to this, there arose a large number of similar but smaller groups, particularly throughout the Middle West. Of all the many clinics that have developed however, only three have reached national and international prominence. These are the Mayo Clinic, the Crile Clinic, of Cleveland, and the Lahey Clinic, of Boston. In addition to the excellence in the quality of medicine provided, these clinics have one common and apparently essential factor—the presence of an unusually able and dynamic leader—in each case a surgeon—who has excelled not only professionally but in the organization, selection and

he management of personnel necessary to the success of the undertaking

Contract-service system In 1929, Dr. Donald E. Ross and Dr. H. Clifford Loos, of Los Angeles, were approached by members of the Department of Water and Power of that city concerning the possibility of organizing for them a medical service, financed through periodic payments. With this stimulus, the Ross-Loos Clinic group was formed and began to function on April 1, 1929. For a monthly fee of \$1.50 — later raised to \$2.00 — for each subscriber, the group agreed to provide medical service, including attention either from a general practitioner or a specialist in the central offices or the hospital, or in the subscriber's home if the patient was unable to come to the clinic. Subscribers were to receive laboratory and x-ray services, physical therapy, ambulance service, drugs, dressings and hospitalization in a ward bed. Additional charges were made for certain services, such as dental work, special drugs and appliances.

In 1934, Dr. Ross and Dr. Loos were expelled from the Los Angeles County Medical Society not because the clinic was engaged in contract practice but because it was alleged that there was a solicitation of patients. The expulsion was sustained by the California Medical Association, which automatically brought suspension from the American Medical Association. According to the constitution of the latter, such expulsion is subject to appeal before the Judicial Council. This appeal was made, and on January 2, 1936, the action of the county and state societies was overruled. The conclusions reached by the Judicial Council were as follows:

a. The appellants were brought to trial with no definite knowledge of what they were charged.

b. There was no adequate opportunity to defend themselves.

c. They were expelled for some unknown act not appearing in the charges.

d. They did not have a fair trial.

Following this action by the Judicial Council, the two physicians were reinstated by the county medical society.

At the present writing there are one hundred and ten full-time doctors of medicine in the group, all of whom are members of the county medical society and therefore of the American Medical Association. Dr. Loos is a member of the House of Delegates of the California Medical Association and holds an important chairmanship in the local society; indeed, it is said that a most cordial relation exists between the physicians of the clinic and other doctors in the area. The clinic provides service for about 110,000 people in the Los Angeles area. The cost to the subscriber is \$2.50 a month. Dependents of subscribers are not included in this fee, but are accorded care at special rates — for example, office consultation or treatment, 75 cents; refraction, \$1.00; residence calls, daytimes, \$1.50, and nights (between 9:00

p.m. and 8:00 a.m.), \$2.00; minor operations, \$15.00, and major operations, \$25.00.

The above group and others similarly organized and controlled maintain excellent standards of medical service. Unfortunately, there developed in many communities groups supposedly organized on the same basis but actually organized by lay promoters, patronage being secured by advertising and solicitation. Where such organizations have developed, competition for patronage has resulted in a reduction of premiums and a lowering of the quality of medical care. In one state one hundred and forty-three such organizations were promoted as medical-service plans, with lay promoters acting as medical brokers and in some instances contracting with clinics or private groups of physicians in hospitals for the services promised to the prospective patient. In other groups no medical contracts were made and therefore no medical services were available to the enrolled members.

Nonprofit Prepayment Hospital-Service and Medical-Service Plans (Blue Cross and Blue Shield)

"Back in 1929, when Baylor had an idea that hospital costs could best be borne by group action, a budget plan for meeting certain but unpredictable hospital bills was established." This quotation is from a letter written in August, 1944, by Lawrence Paine, administrator of Baylor University Hospital of Dallas, Texas, and gives the beginning of what has become known as the Blue Cross program. Group Hospital Service, Incorporated, of Dallas, was inaugurated on a statewide basis in 1939 and experienced a phenomenal growth, but two years later was confronted with a deficit of \$110,000. Then followed a period of readjustment, and one year later Group Hospital Service was pronounced financially sound.

The Blue Cross program, as it has come to be known, was designed to cover the cost of hospitalization for patients in the lower-income groups who went into hospitals at so-called "semiprivate" accommodations. It covers either individuals or families, and usually includes all the ordinary costs payable to the hospital for a given period of time, generally three weeks. Persons must join in groups. The organization is on a nonprofit basis, and the cost for its protection is about 85 cents a month for an individual and \$2.00 for family membership. At the present time approximately 18,000,000 persons in this country subscribe to the program.

In addition to the Blue Cross program there are medical-service plans, most of them sponsored by the medical societies of various states. One of the largest and most successful of these is Michigan Medical Service, which was organized on a statewide basis by the Michigan State Medical Society in 1940. When first established, it gave, in conjunction with Michigan Hospital Service, complete hospital, medical and surgical services to subscribers

and their families. There is no income limitation on eligibility to enroll, but if the income of an unmarried subscriber is more than \$2000 or that of a married one is more than \$2500, the amounts allowed may not be adequate to cover the entire professional fee. In 1942, the Michigan Medical Service had to discontinue its medical coverage in favor of surgical coverage only. There is ample actuarial experience for the successful establishment of a surgical plan. The problems involved in sound actuarial medical plans have, however, not yet been satisfactorily solved, although all plans look forward to the inclusion of medical services as increasing experience permits. To us in Massachusetts, it is encouraging to learn that in the first quarter of 1945 the Massachusetts Medical Service — established by the Massachusetts Medical Society — had the largest net enrollment of any medical society plan in the country, and that in the near future it anticipates the inclusion of medical care in the hospital without an increase in rates.

In addition to the Blue Cross and Blue Shield programs, a large number of projects under the stimulus and guidance of medical groups are being put into practice throughout the country. Thus, the State Medical Society of Wisconsin is actively working at the present time on a plan to provide complete coverage to low-income groups throughout the entire state.

Medical Committees

The Committee of Physicians for the Improvement of Medical Care, Incorporated. This committee was formed in 1937 by a small but well known group of physicians, many of them in the field of medical education. They believe that "the health of the people is a direct concern of the Government." This committee has taken an active part in an attempt to outline the principles of an improved medical practice. Its communications have been few but dignified and constructive, although many times not in agreement with current medical thought. Its letter of congratulation to Senator Wagner after the introduction of his bill (S 1161) suggests that the committee was willing at that time to favor the adoption of a compulsory federal health system.

The National Physicians Committee for the Extension of Medical Service. This committee was established in 1939. Most if not all of its members, too, are well known in medical circles, although they are more representative of medical practice than of medical education. This committee has no direct affiliation or working connection with the American Medical Association, but its principles have been endorsed by the House of Delegates of the Association and active in its work are some who are or have been actively interested in the American Medical Association. The National Physicians Committee believes that the necessary and desirable steps to improve and spread the cost of medical

care can best be done within the framework of principles approved by the medical profession. It favors state and local rather than federal subsidies to the indigent. The committee has been criticized for its violent attack on the Murray-Wagner Dingell Bill. Its widely heralded opposition to S 1161 and the committee-sponsored polls by the Opinion Research Corporation, of Princeton, New Jersey, have, however, undoubtedly done much to awaken the medical profession of the country to the need of taking an active part in developing or recognizing an improved medical practice more acceptable to the public who pays for it.

INFLUENCES OUTSIDE THE MEDICAL PROFESSION

Group Insurance for Industrial Workers

In 1912, Montgomery Ward and Company, of Chicago, purchased from an insurance company a group-insurance policy. This provided life insurance for all employees and is said to be the first group life-insurance policy written by any private carrier in this country.

For over twenty-five years, the Endicott-Johnson Shoe Company, of Binghamton, New York, has provided full medical care and hospitalization for all workers and their dependents, without cost. Between that time and the present, there has developed an increasing interest on the part of industry in the type of medical care given to employees and their dependents, and in 1943, according to a recent survey of the National Physicians Committee, there was a total of nonduplicated insurance — including the Blue Cross — in this country covering more than 25,000,000 persons. The coverage in the various policies varies tremendously, as does the proportion of the cost paid by the worker and by the employer. It has been suggested that complete group health insurance might consist of the following for employees, life insurance, equal to approximate annual earnings, sickness benefits equal to 25 to 50 per cent of the weekly wage, hospitalization from \$4 to \$7 a day, hospital extras from \$20 to \$35 for each illness, surgical care on the basis of a fee schedule (maximum, \$150), medical care with a fixed maximum benefit and a retirement annuity based on service earnings, and for dependents, identical coverage for hospitalization and surgical and medical care.

There are, however, definite weaknesses in each of the group policies now available through private companies. Outstanding among these weaknesses are the facts that too large a group is required to obtain minimum costs and that insurance protection may be forfeited when employment ceases.

Outstanding in its accomplishments is the highly successful prepaid medical plan that has been set up by Dr. Sidney Garfield at the direction of Mr. Kaiser for his shipbuilders in California (Southern Permanente Foundation) and Washington (North-

n Permanente Foundation) In the Oakland California plant 62,000 of the workers (90 per cent) have joined the plan which is voluntary. Excellent and complete care is given in their own hospitals because of war-time limitations the families of the workers are not included. The organization works in complete harmony with the local medical profession.

Group Health Association, Incorporated

This association was granted a charter in Washington, D. C., in February 1937, with an appropriation of \$40,000 from the Home Owners' Loan Corporation. Through a staff of hired physicians, it proposed to offer to federal employees and their families most types of medical and surgical care at a stated annual cost. The Medical Society of the District of Columbia opposed this scheme believing that it was not to the best interests of the public or the physician and was in violation of its code of ethics. According to an article that appeared in the *Journal of the American Medical Association* just before the Group Health Association began to function actively, it was thought that the organization was practicing medicine illegally and that the physicians employed were primarily the agents of the association and not those of the patients and that since the bylaws provide that the medical director shall render such reports as the Board of Trustees shall require, all privacy and secrecy between physician and patients would be destroyed. It was also held that there was no opportunity for the freedom of choice of his physician by the patient. One of the members of the Medical Society of the District of Columbia was therefore expelled, and several other physicians resigned from the association. Following this, the American Medical Association and others were indicted by the Department of Justice and were convicted of violating the Sherman Anti-Trust Act. This conviction was upheld by the United States Supreme Court.

PROPOSED CHANGES

Murray-Wagner-Dingell Bill

On June 3, 1943, Senator Wagner — for himself and Senator Murray — presented a bill (S 1161) framed to broaden the present Social Security Act. It included a provision for medical care supported through payroll deductions for the employed and direct taxation for the self-employed.

According to the committee appointed by the American Bar Association to study and report on this bill, its authors are Isadore S. Falk and Wilbur J. Cohen, director and assistant director, respectively of the Bureau of Research and Statistics of the Social Security Board, and Philip Levy, secretary to Senator Wagner. It may therefore be assumed to represent the opinion of the Social Security group concerning the manner in which the health of an individual can be best protected. It provides

complete medical and hospital care for approximately 110,000,000 persons. It provides for an advisory health council to be appointed by the Surgeon General of the United States Public Health Service whose members are authorized to advise him with reference to carrying out the provisions of the act. It provides aid for research and for undergraduate and postgraduate education. It puts complete responsibility for carrying out its provisions on the Surgeon General.

The bill met with violent opposition from many quarters — the American Medical Association, the National Physicians Committee, the American Bar Association, most business organizations and many others who saw in it the centralization of medicine as the initial step toward more complete centralization of all American activities. Organized labor, the National Farmers Union and most social workers favored its passage. It has not been and probably will not be reported from committee.

Pepper Committee Report

The Senate Subcommittee on Wartime Health and Education, with Senator Claude Pepper as chairman, has recently reported on the investigation by this committee of the health of the Nation. It emphasizes that its findings are preliminary. It recommends that federal grants-in-aid be made to the states for the construction of hospitals, medical centers and health centers in accordance with integrated states' plans approved by the United States Public Health Service. It reports an acute shortage of personnel with training in psychology and psychiatry and points out the need of increasing such personnel. It recommends that federal scholarships or loans be made available to qualified students, and urges an increased enrollment of women in medicine, dentistry and so forth. It makes no specific recommendations in regard to health insurance, but points out the importance of group financing. The report states:

Any method which is evolved should offer complete medical care, should be reasonably but not "cut rate" in cost, should include substantially all of the people, should afford the highest quality of care, should permit free choice of physicians or groups of physicians, should allow democratic participation in policy making by consumer and producers, should be adaptable to local conditions and needs and should provide for continuous experimentation and improvement.

The report is well written and suggests that the work and recommendations of this committee should be carefully followed by all those interested in the future of medical practice.

* * *

In closing, let me remind you that the practice of medicine as you will know it may differ in many ways from that which we know today. There are many forces at work both within and outside medicine to give all the people of this country the best possible medical care at a cost within their

n Permanente Foundation) In the Oakland California, plant, 62 000 of the workers (90 per cent) have joined the plan, which is voluntary. Excellent and complete care is given in their own hospitals because of war-time limitations the families of the workers are not included. The organization works in complete harmony with the local medical profession.

Group Health Association, Incorporated

This association was granted a charter in Washington, D. C., in February, 1937, with an appropriation of \$40,000 from the Home Owners' Loan Corporation. Through a staff of hired physicians, it proposed to offer to federal employees and their families most types of medical and surgical care at a stated annual cost. The Medical Society of the District of Columbia opposed this scheme, believing that it was not to the best interests of the public or the physician and was in violation of its code of ethics. According to an article that appeared in the *Journal of the American Medical Association* just before the Group Health Association began to function actively, it was thought that the organization was practicing medicine illegally and that the physicians employed were primarily the agents of the association and not those of the patients and that since the bylaws provide that the medical director shall render such reports as the Board of Trustees shall require, all privacy and secrecy between physician and patients would be destroyed. It was also held that there was no opportunity for the freedom of choice of his physician by the patient. One of the members of the Medical Society of the District of Columbia was therefore expelled, and several other physicians resigned from the association. Following this, the American Medical Association and others were indicted by the Department of Justice and were convicted of violating the Sherman Anti-Trust Act. This conviction was upheld by the United States Supreme Court.

PROPOSED CHANGES

Murray-Wagner-Dingell Bill

On June 3, 1943, Senator Wagner — for himself and Senator Murray — presented a bill (S 1161) framed to broaden the present Social Security Act. It included a provision for medical care supported through payroll deductions for the employed and direct taxation for the self-employed.

According to the committee appointed by the American Bar Association to study and report on this bill, its authors are Isadore S. Falk and Wilbur J. Cohen, director and assistant director, respectively of the Bureau of Research and Statistics of the Social Security Board, and Philip Levy, secretary to Senator Wagner. It may therefore be assumed to represent the opinion of the Social Security group concerning the manner in which the health of the country can be best protected. It provides

complete medical and hospital care for approximately 110 000,000 persons. It provides for an advisory health council to be appointed by the Surgeon General of the United States Public Health Service whose members are authorized to advise him with reference to carrying out the provisions of the act. It provides aid for research and for undergraduate and postgraduate education. It puts complete responsibility for carrying out its provisions on the Surgeon General.

The bill met with violent opposition from many quarters — the American Medical Association, the National Physicians Committee, the American Bar Association, most business organizations and many others who saw in it the centralization of medicine as the initial step toward more complete centralization of all American activities. Organized labor, the National Farmers Union and most social workers favored its passage. It has not been and probably will not be reported from committee.

Pepper Committee Report

The Senate Subcommittee on Wartime Health and Education, with Senator Claude Pepper as chairman, has recently reported on the investigation by this committee of the health of the Nation. It emphasizes that its findings are preliminary. It recommends that federal grants-in-aid be made to the states for the construction of hospitals, medical centers and health centers in accordance with integrated states' plans approved by the United States Public Health Service. It reports an acute shortage of personnel with training in psychology and psychiatry and points out the need of increasing such personnel. It recommends that federal scholarships or loans be made available to qualified students, and urges an increased enrollment of women in medicine, dentistry and so forth. It makes no specific recommendations in regard to health insurance, but points out the importance of group financing. The report states

Any method which is evolved should offer complete medical care, should be reasonably but not "cut rate" in cost, should include substantially all of the people, should afford the highest quality of care, should permit free choice of physicians or groups of physicians, should allow democratic participation in policy making by consumer and producers, should be adaptable to local conditions and needs and should provide for continuous experimentation and improvement.

The report is well written and suggests that the work and recommendations of this committee should be carefully followed by all those interested in the future of medical practice.

* * *

In closing, let me remind you that the practice of medicine as you will know it may differ in many ways from that which we know today. There are many forces at work both within and outside medicine to give all the people of this country the best possible medical care at a cost within their

reach. There is common acceptance of this objective, but there are widely divergent views concerning the best methods of attaining it. I shall only add that the actual care received by a given patient will always depend on the character and ability of the individual physician, the quality of his training in school and during the early years after graduation

the conditions under which he practices, and the opportunities and incentives for continued educational advancement, and that any changes in medical practice that do not have as their primary objective a continued improvement in the quality of service given may well lower rather than elevate the standard of health of the American people

CASE 32061

PRESENTATION OF CASE

A fifty-year-old theater manager entered the hospital complaining of vomiting of blood.

Five months before admission he felt nauseated and vomited a large blood clot. After this episode he felt well until six weeks later, when he again experienced severe nausea and vomited a large quantity of blood. During the following three days he had four more massive hematemeses, with tarry stools. He had received several blood transfusions.

The past history revealed that for years the patient had complained of upper abdominal pain, gaseous eructations and nausea. At the age of thirty-five an exploratory laparotomy because of continued discomfort revealed a "bulbous growth on the appendix," and an appendectomy was performed. Twelve years before admission the patient had five pleural effusions in one year and was sent to a sanatorium for eleven months. For about one and a half years after discharge he had no pain. Ten years before admission, attacks of severe epigastric pain, nausea and flatulence began. They were not related to meals, frequently occurring at night. The pain usually began in the right costovertebral angle but then spread anteriorly over the right upper quadrant, with some radiation across the left side and toward the back. The pain was not relieved by alkalis or a bland diet but was always relieved by vomiting. Two years before admission a gastric aspiration revealed acid-fast bacilli. He again went to a sanatorium, where the sputum and gastric juice were each positive on one occasion. During the fifteen months before admission the gastric juice was negative for acid-fast bacilli.

Physical examination revealed the patient to be well developed and nourished and in no distress. The heart, lungs and abdomen were normal.

The temperature was 97.4°F, the pulse 82, and the respirations 18. The blood pressure was 108 systolic, 70 diastolic.

The red-cell count was 4,860,000, with 14.3 gm. of hemoglobin. The white-cell count was 12,700. The urine was normal, as were the blood chemical findings. Gastric analysis revealed 5 units of free hydrochloric acid in the first specimen, 15 units in the second and 79 units in the third. The gastric juice was guaiac negative and contained no acid-fast bacilli by the alum flocculation method.

A gastrointestinal series showed no evidence of esophageal varices or of hiatus hernia. The stomach was normal in form and function. Barium passed the pylorus without delay, filling the duodenal bulb to a normal contour. The tip of the bulb, however, was consistently deformed, especially when the bulb was collapsed. A definite ulcer crater could not be found. Barium passed rapidly through the small bowel. A barium enema was essentially negative.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: Before seeing the x-ray films we might summarize this story. This man began to bleed five months before admission, vomiting a little blood. Six weeks later he had recurrent, apparently massive, hemorrhages over a period of three days. He vomited blood, and he passed bloody stools. He had several blood transfusions. Although it does not so state, I presume that it is fair to assume that he had had no bleeding for approximately three and a half months. In the past he had had a good deal of abdominal pain, which to me is indefinite in character and means nothing so far as pointing to a diagnosis is concerned. It was not characteristic of a duodenal ulcer or of gallstones, indeed, it was not characteristic of anything and means nothing to me at the moment. This man had acid-fast bacilli in the sputum. I presume that tuberculosis alone would not be adequate for a diagnosis. I do not believe, however, that we should spend more time on it, it probably does not enter into our problem, since we do not have to decide whether the patient should be operated on. I think we can safely assume that the blood came from the upper gastrointestinal tract and not from the bronchial tree.

DR MILFORD D SCHULZ Then I shall just tuck this x-ray film of the chest down in the corner

DR MCKITTRICK I am constantly looking with great expectation to the day when the radiologist helps me at this stage of the game

DR SCHULZ I do not believe that this is the time these are the films of the colon, made on two successive days The second examination was made because of a defect seen near the splenic flexure It is no longer evident on the second examination These are films of the lower esophagus and they show no evidence of varices The stomach is quite normal in appearance The only thing seen is the deformity of the distal portion of the duodenal bulb, but there is no evidence of an active ulcer crater The duodenal loop is entirely normal in appearance There is nothing abnormal in the appearance of the small bowel

DR MCKITTRICK Thank you, sir I continue to appreciate your efforts

I might say right now that I am not going to make a diagnosis because I do not know what this man had The blood that he vomited probably came from the stomach or duodenum I say that simply because we have no evidence that it could have come from any place else There were no symptoms or evidence suggestive of anything in the esophagus he did not have varices demonstrable by x-ray, and no hiatus hernia Without symptoms referable to the esophagus and without evidence of a lesion of the esophagus by x-ray, the esophagus is out of the picture so far as I am concerned We know that the blood could not have come from a site much lower than the duodenum because most of it was vomited Therefore, we are not concerned with anything below the level of the duodenum That narrows the field to the stomach and the duodenum, and there is something more than the fact that this is a conference case that makes me suspicious that what the x-ray films show was not the cause of this man's bleeding This is only a suspicion because there is nothing definite to go on

The patient had vomited blood with blood clots on one occasion Possibly that is more suggestive of the stomach than the duodenum, but I am not sure of it I completely distrust his story so far as it has anything to do with the present situation The bleeding might have been due to a duodenal ulcer, or it might not There is, as you know, a lesion sometimes called duodenal ulcer occulta, an ulcer in the second portion of the duodenum in the region of the ampulla The symptoms in such cases are indefinite, the patient may be operated on for almost anything except duodenal ulcer, and the ulcer is apt to be missed at operation unless the surgeon is particularly on the alert This may be one of these cases, but I doubt it We do not have the benefit of x-ray examination promptly after the hemorrhage Careful x-ray study at such a time is particularly useful

It has been my very limited experience that when I am not able definitely to demonstrate from the clinical evidence the source of a man's bleeding I am apt to be disappointed at operation A gastroscopy was not done I do not know of any reason why it should have been done I presume that if this man had active gastritis it probably would have shown by x-ray examination although all the acute episodes happened three and a half months before entry Since I have to make a diagnosis, I shall have to call the lesion a duodenal ulcer because of the deformity shown at x-ray examination, but I shall quickly add that this is probably wrong I am strongly suspicious that the bleeding came from the stomach If it came from the stomach it could have been caused by any one of a number of things including an ulcer or gastritis that had healed I believe it was likelier due to a lesion that was missed by x-ray examination Even the X-ray Department does occasionally miss a definite lesion of the stomach I do not believe however, that it often misses an ulcer or a carcinoma, but something like a leiomyoma is sometimes difficult to spot particularly if it is small I have to leave it at that

I will say that this man had a healed duodenal ulcer but I am suspicious that tucked away in the stomach some place there was a lesion from which this man bled

DR TRACY B MALLORY Are there any other suggestions?

A PHYSICIAN Was this man an alcoholic?

DR GORDON A DONALDSON No

DR MALLORY Will you tell us about the operative findings, Dr Donaldson?

DR DONALDSON We were just as unhappy about the diagnosis as Dr McKittrick is There were many points in favor of a duodenal ulcer We thought that the bleeding was typical of the upper gastrointestinal tract and this patient was a perfect type for an ulcer since he was a thin asthenic, theatrical manager, with a high gastric acidity

We were also interested in the upper abdominal cramps, which he had had for years, and at operation, Dr Allen carefully explored the ileocecal region The vessels over the serosa were definitely dilated, but the bowel wall seemed to be essentially normal We thought that the bleeding could not have come from that source There was an avascular adhesion between the gall bladder and the duodenum, which was cut, and the duodenum was thoroughly explored without finding any evidence of induration or ulceration He then turned his attention to the stomach itself, and while he was exploring the mesenteric border, high on the lesser curvature the cause of the bleeding was found

CLINICAL DIAGNOSIS

Duodenal ulcer

DR MCKITTRICK'S DIAGNOSIS

Duodenal ulcer

reach. There is common acceptance of this objective, but there are widely divergent views concerning the best methods of attaining it. I shall only add that the actual care received by a given patient will always depend on the character and ability of the individual physician, the quality of his training in school and during the early years after graduation

the conditions under which he practices, and the opportunities and incentives for continued educational advancement, and that any changes in medical practice that do not have as their primary objective a continued improvement in the quality of service given may well lower rather than elevate the standard of health of the American people

CASE 32061

PRESENTATION OF CASE

A fifty-year-old theater manager entered the hospital complaining of vomiting of blood.

Five months before admission he felt nauseated and vomited a large blood clot. After this episode he felt well until six weeks later, when he again experienced severe nausea and vomited a large quantity of blood. During the following three days he had four more massive hematemeses, with tarry stools. He had received several blood transfusions.

The past history revealed that for years the patient had complained of upper abdominal pain, gaseous eructations and nausea. At the age of thirty-five an exploratory laparotomy because of continued discomfort revealed a "bulbous growth on the appendix," and an appendectomy was performed. Twelve years before admission the patient had five pleural effusions in one year and was sent to a sanatorium for eleven months. For about one and a half years after discharge he had no pain. Ten years before admission, attacks of severe epigastric pain, nausea and flatulence began. They were not related to meals, frequently occurring at night. The pain usually began in the right costovertebral angle but then spread anteriorly over the right upper quadrant, with some radiation across the left side and toward the back. The pain was not relieved by alkalis or a bland diet but was always relieved by vomiting. Two years before admission a gastric aspiration revealed acid-fast bacilli. He again went to a sanatorium, where the sputum and gastric juice were each positive on one occasion. During the fifteen months before admission the gastric juice was negative for acid-fast bacilli.

Physical examination revealed the patient to be well developed and nourished and in no distress. The heart, lungs and abdomen were normal.

The temperature was 97.4°F, the pulse 82, and the respirations 18. The blood pressure was 108 systolic, 70 diastolic.

The red-cell count was 4,860,000, with 14.3 gm. of hemoglobin. The white-cell count was 12,700. The urine was normal, as were the blood chemical findings. Gastric analysis revealed 5 units of free hydrochloric acid in the first specimen, 15 units in the second and 79 units in the third. The gastric juice was guaiac negative and contained no acid-fast bacilli by the alum flocculation method.

A gastrointestinal series showed no evidence of esophageal varices or of hiatus hernia. The stomach was normal in form and function. Barium passed the pylorus without delay, filling the duodenal bulb to a normal contour. The tip of the bulb, however, was consistently deformed, especially when the bulb was collapsed. A definite ulcer crater could not be found. Barium passed rapidly through the small bowel. A barium enema was essentially negative.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. LELAND S. MCKITTRICK: Before seeing the x-ray films we might summarize this story. This man began to bleed five months before admission, vomiting a little blood. Six weeks later he had recurrent, apparently massive, hemorrhages over a period of three days. He vomited blood, and he passed bloody stools. He had several blood transfusions. Although it does not so state, I presume that it is fair to assume that he had had no bleeding for approximately three and a half months. In the past he had had a good deal of abdominal pain, which to me is indefinite in character and means nothing so far as pointing to a diagnosis is concerned. It was not characteristic of a duodenal ulcer or of gallstones, indeed, it was not characteristic of anything and means nothing to me at the moment. This man had acid-fast bacilli in the sputum. I presume that tuberculosis alone would not be adequate for a diagnosis. I do not believe, however, that we should spend more time on it, it probably does not enter into our problem, since we do not have to decide whether the patient should be operated on. I think we can safely assume that the blood came from the upper gastrointestinal tract and not from the bronchial tree.

series of films I have a few questions that I should like to ask him. I have not seen the films.

DR CLAYTON H. HALE: Unfortunately the films were all taken with the patient in bed and are not entirely satisfactory. We have here a heart that is somewhat enlarged, especially in the region of the ventricles. The aorta is tortuous, and there is a suggestion in one of the films that the ascending aorta is slightly widened.

DR BLAND: Three sets of films are described. I am particularly interested in the one taken on admission.

DR HALE: In the first film there is a rather hazy area of density in the left lower lobe and a fairly tortuous aorta. The right hilum is more prominent than the left. I do not believe that we have ever made a preautopsy diagnosis of massive pulmonary embolus by x-ray examination, although a review of the films of some of these cases has suggested that the involved pulmonary artery was larger than normal. We cannot make such a diagnosis from these films, but one would have to think of it as a possibility. The shadow in the lungs is not typical of an infarct. On the lateral film taken two days later you can again see an area of density, but this also does not look like an infarct. It looks more like an area of atelectasis in the lower lobe. The costophrenic sinus is slightly obscured, possibly by a small amount of fluid.

Another diagnosis that we have trouble in making by x-ray examination is dissecting aneurysm of the aorta. Looking back over the films of some of these cases, after the diagnosis has been proved, has suggested to us that the loss of definition of the descending aorta in the lateral projection may be a significant sign in making a diagnosis of dissecting aneurysm of the aorta. On the lateral chest films of this case the descending aorta is not clearly seen, but these are not good films, so that I do not know how much we should depend on the sign in this case.

To sum up what I have said, this man had a large heart, with no evidence of pulmonary edema. I see no characteristic shadows of infarcts. I interpret the shadow in the lower lobe as consistent with atelectasis, and the ascending aorta looks widened. This undoubtedly was a sclerotic aorta. The significance of the prominent right pulmonary artery is questionable. The absence of sharp definition of the aortic shadow below this point in the descending aorta must make one think of the possibility of a dissecting aneurysm, but one cannot safely make this diagnosis because of the poor quality of the available films.

DR BLAND: Do you want to comment on this streak in the left upper chest?

DR HALE: I should think that it was a small area of atelectasis.

DR BLAND: Could it represent a healed infarct?

DR HALE: It could, but its shape and location are rather unusual for an infarct.

DR BLAND: In looking back over the history, it is clear that this patient had phlebitis. He had swelling of one leg and pain in the other, so that it must have been a fairly extensive process. I suspect that he had had phlebitis longer than the record indicates, indeed that he had it before he came into the hospital. That is somewhat supported, I think, by the scar in the lung, which looks to me as if it could easily be one of the scars that Dr. Castleman and Dr. Hampton have so well described. He had, in addition to the phlebitis, clinical evidence of pulmonary emboli. The onset of his illness qualifies well. Its abruptness is mildly against coronary thrombosis and much more in favor of a large pulmonary embolus or a dissection of the aorta. The fact that the electrocardiogram, except for the irritability of the heart, was essentially normal should not disturb us too much in the diagnosis of pulmonary embolus.

DR BENJAMIN CASTLEMAN: Two more electrocardiograms were taken that are not recorded in the clinical abstract.

DR BLAND: As I look at them quickly I should say that they are essentially normal. There is no prominence of the S waves in Lead I or of the Q waves in Lead 3, which sometimes occurs during the first few hours after a large embolus. There is no inversion of the T waves in Lead 3, and no tendency to right-axis deviation. It should be remembered, however, that only about 10 per cent of patients with pulmonary embolus get acute cor pulmonale and that we believe the electrocardiogram is simply a reflection of the acute dilatation of the right side of the heart. It is evidence of considerable weight against coronary thrombosis, and it helps us only in a negative fashion in our consideration of possible dissection of the aorta.

When we examine the recorded findings in the heart for evidence of acute cor pulmonale, in addition to the electrocardiogram, the usual things that we look for are not commented on — namely, accentuation of the pulmonic second sound, and gallop rhythm — and certain murmurs that we should not expect to find in this condition are mentioned. Tachycardia and irritability of the heart are quite frequent with pulmonary emboli. Usually it is ventricular irritability that predominates. Therefore, we must conclude that there is nothing in the heart on first examination to indicate acute right-sided dilatation. The patient's subsequent course, however, indicates that he must have had pulmonary emboli and infarction. The transient changes described in the x-ray films seem to fit in very well with Dr. Hampton and Dr. Castleman's description of incomplete infarction of the lung, in which the shadows clear up quickly, thus indicating functional infarction without actual destruction of the pulmonary tissue. Then, of course, the

ANATOMICAL DIAGNOSIS

Neurinoma of stomach

PATHOLOGICAL DISCUSSION

DR MALLORY This was a tumor of the stomach wall. It projected only externally from the muscle layer, which explains the failure of the X-ray Department to visualize it. There was a slight crater—a shallow ulceration of the mucosa just over the tumor. If that had been caught in a certain plane, it might have been demonstrable.

The tumor was of the spindle-cell type, which pathologists usually argue about—whether it is a leiomyoma or tumor of nerve-sheath origin. We classified this as a neurinoma, which is, in my opinion, the more frequent of the two tumors in the stomach. It was slowly growing and can safely be called benign. There is not much doubt that the man is cured.

CASE 32062

PRESENTATION OF CASE

A fifty-year-old pipefitter was admitted to the hospital complaining of substernal pain.

One hour before admission he was doing his regular work at the Navy Yard but exerting himself more than usual. He was suddenly overcome by a sensation of heavy substernal compression. He felt weak and sat down. He was taken to the Infirmary, where he was given 16 mg of morphine sulfate. He was then brought to the Emergency Ward, where he complained of substernal pain radiating to both scapulas.

The past history revealed that a year before admission the patient was treated at another hospital for olecranon bursitis. At that time the blood pressure was not recorded. The heart was not enlarged, and the pulse was 70 and regular. There were no cardiac murmurs. A Kahn test was negative. Twelve years before admission he was found to have a systolic blood pressure of 185, which decreased after treatment. Eighteen years before admission he was treated for a urethral stricture, but he denied venereal disease. At no time had there been any evidence of cardiac failure.

Physical examination revealed the patient to be apprehensive and pale. He was not dyspneic. The skin was moist. The heart was enlarged to the left, but the border was difficult to percuss. Extrasystoles were frequent, with occasional runs of eight or more. A Grade I systolic murmur and a Grade II diastolic murmur were heard at the apex. At the base, over the sternum, was heard a Grade III to-and-fro murmur, loudest in diastole. There were no thrills, and no carotid transmission. The lungs and abdomen were normal. There was no ankle edema.

The temperature was 98°F, the pulse 84, and the respirations 20. The blood pressure was 160 systolic, 100 diastolic.

The red-cell count was 5,300,000, with 14.5 gm of hemoglobin. The white-cell count was 13,400, with 87 per cent neutrophils. The urine gave a ++ test for albumin, and the sediment contained an occasional white cell.

An x-ray film of the chest taken on the first hospital day showed an area of increased density lateral to the apex of the heart and in the cardiophrenic angle. Above this, at the level of the left hilus, there was a linear shadow of increased density. The aorta was rather tortuous. Another film, taken on the second hospital day, showed a similar picture, with a small area of hazy density at the left base. A third film, taken on the day before death, showed that this area had almost completely disappeared. An electrocardiogram showed normal rhythm, with a rate of 100. Evidence of left axis deviation was present. The PR interval was 0.16 second. There were many premature beats in Leads 1 to 2 that originated from varying ventricular foci. The T waves were upright in Leads 1 and 2 and in the precordial lead but flat in Lead 3. QRS was slurred. There was a run of ventricular tachycardia in CF.

Soon after admission 0.2 gm of quinine sulfate was ordered every four hours. Ten hours after admission, the patient was much improved, sleeping well and exhibiting a much more regular cardiac rhythm. The extrasystoles, however, persisted. He complained of no pain. On the second hospital day the left calf was noted to be tender, and the right swollen. The temperature rose to 105°F. He complained of pain in the left chest on respiration, and bloody sputum was noted. The breath sounds were diminished over the left lower lobe. A bilateral femoral-vein ligation was done. After the operation he felt well, and the temperature returned to normal.

On the morning of the fifth hospital day the patient was in a cheerful mood, having spent a comfortable night. As the nurse was about to give him breakfast, he suddenly complained of pain in the back. He then began to breathe deeply, became flushed and died in a few seconds.

DIFFERENTIAL DIAGNOSIS

DR EDWARD F BLAND The abruptness of the onset of illness in this previously well man and his sudden and unexpected demise a few days later, with pain, breathlessness and collapse, point unmistakably to a major vascular accident. The likeliest possibilities that immediately come to mind are pulmonary embolus, coronary thrombosis and dissecting aneurysm of the aorta. It is perhaps unnecessary to go beyond those three conditions in a discussion of the differential diagnosis. There are some clinical details, however, that are puzzling and warrant special comment.

Before we embark on the discussion, may we see the x-ray films? After Dr Hale has presented the

ries of films I have a few questions that I should like to ask him. I have not seen the films.

DR CLAYTON H. HALE: Unfortunately the films are all taken with the patient in bed and are not entirely satisfactory. We have here a heart that is somewhat enlarged, especially in the region of the ventricles. The aorta is tortuous, and there is suggestion in one of the films that the ascending aorta is slightly widened.

DR BLAND: Three sets of films are described. I am particularly interested in the one taken on admission.

DR HALE: In the first film there is a rather hazy area of density in the left lower lobe and a fairly tortuous aorta. The right hilum is more prominent than the left. I do not believe that we have ever made a preautopsy diagnosis of massive pulmonary embolus by x-ray examination, although a review of the films of some of these cases has suggested that the involved pulmonary artery was larger than normal. We cannot make such a diagnosis from these films, but one would have to think of it as a possibility. The shadow in the lungs is not typical of an infarct. On the lateral film taken two days later you can again see an area of density, but this also does not look like an infarct. It looks more like an area of atelectasis in the lower lobe. The costophrenic sinus is slightly obscured, possibly by a small amount of fluid.

Another diagnosis that we have trouble in making by x-ray examination is dissecting aneurysm of the aorta. Looking back over the films of some of these cases, after the diagnosis has been proved, has suggested to us that the loss of definition of the descending aorta in the lateral projection may be a significant sign in making a diagnosis of dissecting aneurysm of the aorta. On the lateral chest films of this case the descending aorta is not clearly seen, but these are not good films, so that I do not know how much we should depend on the sign in this case.

To sum up what I have said, this man had a large heart, with no evidence of pulmonary edema. I see no characteristic shadows of infarcts. I interpret the shadow in the lower lobe as consistent with atelectasis, and the ascending aorta looks widened. This undoubtedly was a sclerotic aorta. The significance of the prominent right pulmonary artery is questionable. The absence of sharp definition of the aortic shadow below this point in the descending aorta must make one think of the possibility of a dissecting aneurysm, but one cannot safely make this diagnosis because of the poor quality of the available films.

DR BLAND: Do you want to comment on this streak in the left upper chest?

DR HALE: I should think that it was a small area of atelectasis.

DR BLAND: Could it represent a healed infarct?

DR HALE: It could, but its shape and location are rather unusual for an infarct.

DR BLAND: In looking back over the history, it is clear that this patient had phlebitis. He had swelling of one leg and pain in the other, so that it must have been a fairly extensive process. I suspect that he had had phlebitis longer than the record indicates, indeed that he had it before he came into the hospital. That is somewhat supported, I think, by the scar in the lung, which looks to me as if it could easily be one of the scars that Dr Castleman and Dr Hampton have so well described. He had, in addition to the phlebitis, clinical evidence of pulmonary emboli. The onset of his illness qualifies well. Its abruptness is mildly against coronary thrombosis and much more in favor of a large pulmonary embolus or a dissection of the aorta. The fact that the electrocardiogram, except for the irritability of the heart, was essentially normal should not disturb us too much in the diagnosis of pulmonary embolus.

DR BENJAMIN CASTLEMAN: Two more electrocardiograms were taken that are not recorded in the clinical abstract.

DR BLAND: As I look at them quickly I should say that they are essentially normal. There is no prominence of the S waves in Lead 1 or of the Q waves in Lead 3, which sometimes occurs during the first few hours after a large embolus. There is no inversion of the T waves in Lead 3, and no tendency to right-axis deviation. It should be remembered, however, that only about 10 per cent of patients with pulmonary embolus get acute cor pulmonale and that we believe the electrocardiogram is simply a reflection of the acute dilatation of the right side of the heart. It is evidence of considerable weight against coronary thrombosis, and it helps us only in a negative fashion in our consideration of possible dissection of the aorta.

When we examine the recorded findings in the heart for evidence of acute cor pulmonale, in addition to the electrocardiogram, the usual things that we look for are not commented on — namely, accentuation of the pulmonic second sound, and gallop rhythm — and certain murmurs that we should not expect to find in this condition are mentioned. Tachycardia and irritability of the heart are quite frequent with pulmonary emboli. Usually it is ventricular irritability that predominates. Therefore, we must conclude that there is nothing in the heart on first examination to indicate acute right-sided dilatation. The patient's subsequent course, however, indicates that he must have had pulmonary emboli and infarction. The transient changes described in the x-ray films seem to fit in very well with Dr Hampton and Dr Castleman's description of incomplete infarction of the lung, in which the shadows clear up quickly, thus indicating functional infarction without actual destruction of the pulmonary tissue. Then, of course, the

pleuritic pain and the blood spitting strongly support this impression. This man's veins were tied. Could he have died of pulmonary embolus if both femoral veins were tied? It does not state in the text the site of ligation, whether it was above or below the femoris profunda. Dr Linton pointed out at Grand Rounds this morning that one group in this hospital prefers the lower site, whereas the other prefers the upper site. It is still possible that a large embolus could have come from the profunda if ligation was below this vein. Dr Linton also mentioned that even after ligation 5 per cent of patients may still have serious pulmonary emboli. I am inclined to think that this patient fits into the group in which an embolus either originated in the profunda or formed above the site of ligation. Does anyone know whether the profunda was below or above the site of ligation in this patient?

DR CASTLEMAN The superficial femoral veins were ligated just below the point where the profunda enters to form the common femoral.

DR BLAND It was possible, then, for an embolus to have come from above the site of the ligature or from the profunda.

We come next to a consideration of coronary thrombosis, and I am willing to exclude that diagnosis rather quickly. The onset was too abrupt. The patient had never had trouble previously. The electrocardiograms do not suggest coronary thrombosis, the patient was well between episodes, and he died abruptly. A few years ago Currens² pointed out the fact that, following pulmonary embolus, the accompanying shock and lowering of blood pressure predispose to coronary thrombosis or myocardial infarction. But as an added complication here that is unlikely.

The third condition is dissection of the aorta. The abrupt onset of pain during physical labor is always suggestive of such, especially when there is radiation of the pain through to the back bilaterally. It is not known whether or not the patient had had hypertension shortly before his illness. No mention is made of arterial pulsations in the legs, but I assume it would have been mentioned if they were absent, because the legs were the object of so much consideration.

DR PAUL D WHITE The pulsations were all right.

DR BLAND Is there anything else that points to aortic dissection? One thing that is disturbing is the diastolic murmur. We have to account for it on some basis, especially if we rely on the statement that it was not there one year before the patient came to the hospital. What could take place in the course of a year in a person who was otherwise in good health that would give a diastolic murmur of this nature? The description is not quite adequate to go into a discussion of whether it was a mitral or an aortic diastolic murmur or possibly came from some other valve. Since it

was so well heard over the base and since mitral diastolic murmurs, even loud ones, are not widely transmitted, I am inclined to think that this murmur came from the aortic valve. It is unlikely that rheumatic infection in a well man at this age could produce this much heart disease in the course of a year, at least a murmur of this degree and nature. It is unlikely that syphilis was responsible. The presence of a negative Kahn test one year before admission is strong evidence against it. What can arise acutely in the heart with a resulting diastolic murmur at the base? In patients with dissecting aneurysm of the aorta the dissection occasionally proceeds in a retrograde fashion, thereby distorting the orifice and resulting in a diastolic murmur. A ruptured aortic valve usually occurs acutely and often gives rise to a high degree of aortic regurgitation. We have no evidence of such here.

DR WHITE The chief murmur was diastolic in time, about Grade II and best heard along the left sternal border. It sounded like the murmur of aortic regurgitation. The systolic murmur was extremely slight.

DR BLAND Do you think that the diastolic murmur might have been overlooked a year before entry?

DR WHITE It was not heard at an outside hospital. We wondered if the examination had been careful enough to exclude it at that time. We did not believe that we could place much reliance on the recent development of the murmur, but nevertheless it was one of the findings seriously considered.

DR BLAND It is disturbing in relation to my favored diagnosis of pulmonary embolism. The weight of clinical evidence, however, favors phlebotrombosis, with multiple pulmonary emboli and a terminal massive embolus.

DR WHITE This patient was obviously a difficult diagnostic problem. In fact the resident, the interns and I all differed in our diagnoses. It would, however, have been helpful for Dr Bland actually to have seen the patient and to have talked with him as we did. All this does not get into the record. The suddenness of the onset was striking. He was working on a cruiser in the Navy Yard in a cold rain and was unusually active that day, at the height of his activity, or just as he stopped, he had a sudden overwhelming pain. It was really severe pain. He described it in different ways on different days, but he told me that he felt as if an atomic bomb had hit him, which was very descriptive and colored my opinion about as much as did anything else. Moreover, the pain radiated to the scapulas. The presence of the aortic diastolic murmur, I thought, was important as well. There seemed to be evidence of pulmonary embolism, because of the x-ray films and the blood-spitting, and yet we were never convinced that that was the diagnosis. We thought that it might have been a red herring or a complication. The picture did

it resemble coronary thrombosis in its onset it was too abrupt. We were also quite sure that with such a severe coronary occlusion there would have been a significant change in the electrocardiogram. I was disappointed after the x-ray diagnosis that the electrocardiogram did not show evidence of an acute cor pulmonale. If he had had a massive pulmonary embolism to produce this picture he ought to have had electrocardiographic evidence

PATHOLOGICAL DISCUSSION

DR CASTLEMAN: The autopsy showed a dissecting aortic aneurysm. The intimal tear was in the ascending aorta—the usual place. The dissection had extended proximally and distally—proximally to the base of the aortic valve around the coronary mouths with some dissection of the coronaries themselves and distally to 4 cm above the bifurca-

FIGURE 1 Photomicrograph Showing Medial Degeneration in the Wall of the Aorta. In the areas outlined by the arrows there is total loss of the coarse black elastic fibers; this occurs before actual cyst formation takes place.

of an acute cor pulmonale, which he did not have. Yet as we went on, we wondered if he might not have been an exception to the rule.

DR BLAND: Which possibility did you favor, Dr. White?

DR WHITE: A dissecting aneurysm of the aorta because of the abrupt onset, the terrific pain and the essentially negative electrocardiogram.

CLINICAL DIAGNOSIS

Dissecting aneurysm of aorta?
Pulmonary embolism?

DR BLAND'S DIAGNOSES

Phlebothrombosis femoral
Pulmonary embolism and infarction

ANATOMICAL DIAGNOSIS

Dissecting aneurysm of aorta with rupture into pericardium

tion of the aorta. It did not reach the iliac arteries, as is so often the case. There was some dissection into the branches at the arch. The aneurysm had ruptured through the adventitia at the level of the intimal tear into the pericardium with resultant cardiac tamponade.

DR WHITE: Were the renal arteries involved?

DR CASTLEMAN: No.

The lungs were quite disappointing. We were unable to find emboli or infarcts.

DR BLAND: But he was spitting blood and had pleuritic pain.

DR CASTLEMAN: There were areas of atelectasis and congestion but nothing that we could call a true infarct. It is quite possible, as you suggested, that they were incomplete infarcts that had begun to disappear. At any rate there was no massive embolus and no large infarct.

DR BLAND: Is that shadow part of the dissection of the aorta?

DR CASTLEMAN: The ascending aorta was diffusely dilated, which may have been the result of hypertension or perhaps a combination of hyper-

pleuritic pain and the blood spitting strongly support this impression. This man's veins were tied. Could he have died of pulmonary embolus if both femoral veins were tied? It does not state in the text the site of ligation, whether it was above or below the femoris profunda. Dr Linton pointed out at Grand Rounds this morning that one group in this hospital prefers the lower site, whereas the other prefers the upper site. It is still possible that a large embolus could have come from the profunda if ligation was below this vein. Dr Linton also mentioned that even after ligation 5 per cent of patients may still have serious pulmonary emboli. I am inclined to think that this patient fits into the group in which an embolus either originated in the profunda or formed above the site of ligation. Does anyone know whether the profunda was below or above the site of ligation in this patient?

DR CASTLEMAN The superficial femoral veins were ligated just below the point where the profunda enters to form the common femoral.

DR BLAND It was possible, then, for an embolus to have come from above the site of the ligature or from the profunda.

We come next to a consideration of coronary thrombosis, and I am willing to exclude that diagnosis rather quickly. The onset was too abrupt. The patient had never had trouble previously. The electrocardiograms do not suggest coronary thrombosis, the patient was well between episodes, and he died abruptly. A few years ago Currens² pointed out the fact that, following pulmonary embolus, the accompanying shock and lowering of blood pressure predispose to coronary thrombosis or myocardial infarction. But as an added complication here that is unlikely.

The third condition is dissection of the aorta. The abrupt onset of pain during physical labor is always suggestive of such, especially when there is radiation of the pain through to the back bilaterally. It is not known whether or not the patient had had hypertension shortly before his illness. No mention is made of arterial pulsations in the legs, but I assume it would have been mentioned if they were absent, because the legs were the object of so much consideration.

DR PAUL D WHITE The pulsations were all right.

DR BLAND Is there anything else that points to aortic dissection? One thing that is disturbing is the diastolic murmur. We have to account for it on some basis, especially if we rely on the statement that it was not there one year before the patient came to the hospital. What could take place in the course of a year in a person who was otherwise in good health that would give a diastolic murmur of this nature? The description is not quite adequate to go into a discussion of whether it was a mitral or an aortic diastolic murmur or possibly came from some other valve. Since it

was so well heard over the base and since mitral diastolic murmurs, even loud ones, are not widely transmitted, I am inclined to think that this murmur came from the aortic valve. It is unlikely that rheumatic infection in a well man at this age could produce this much heart disease in the course of a year, at least a murmur of this degree and nature. It is unlikely that syphilis was responsible. The presence of a negative Kahn test one year before admission is strong evidence against it. What can arise acutely in the heart with a resulting diastolic murmur at the base? In patients with dissecting aneurysm of the aorta the dissection occasionally proceeds in a retrograde fashion, thereby distorting the orifice and resulting in a diastolic murmur. A ruptured aortic valve usually occurs acutely and often gives rise to a high degree of aortic regurgitation. We have no evidence of such here.

DR WHITE The chief murmur was diastolic in time, about Grade II and best heard along the left sternal border. It sounded like the murmur of aortic regurgitation. The systolic murmur was extremely slight.

DR BLAND Do you think that the diastolic murmur might have been overlooked a year before entry?

DR WHITE It was not heard at an outside hospital. We wondered if the examination had been careful enough to exclude it at that time. We did not believe that we could place much reliance on the recent development of the murmur, but nevertheless it was one of the findings seriously considered.

DR BLAND It is disturbing in relation to my favored diagnosis of pulmonary embolism. The weight of clinical evidence, however, favors phlebotrombosis, with multiple pulmonary emboli and a terminal massive embolus.

DR WHITE This patient was obviously a difficult diagnostic problem. In fact the resident, the interns and I all differed in our diagnoses. It would, however, have been helpful for Dr Bland actually to have seen the patient and to have talked with him as we did. All this does not get into the record. The suddenness of the onset was striking. He was working on a cruiser in the Navy Yard in a cold rain and was unusually active that day, at the height of his activity, or just as he stopped, he had a sudden overwhelming pain. It was really severe pain. He described it in different ways on different days, but he told me that he felt as if an atomic bomb had hit him, which was very descriptive and colored my opinion about as much as did anything else. A NEW DEAL FOR THE VETERANS ADMINISTRATION

DURING the past several years many physicians who were not eligible for full military service have been urged to enter the Veterans Administration in a professional capacity. A few brave souls with excellent training in their respective fields accepted this challenge. Fully realizing that certain disadvantages surrounded their decision, they believed that there was a golden opportunity ahead of them. They recognized, on the one hand, that the medical care of veterans has heretofore been inexcusably poor and, on the other hand, that these very men who gave so much to their country deserve the best of medical and surgical care.

Some months ago there was talk of detailing medical officers of the Army and Navy to the Veterans Administration, and indeed several hundred were so transferred, the majority against their wishes. Had this movement been followed through, many of the difficulties of the past would have been eliminated, but as was pointed out in a recent editorial in the *Journal*,* it would be far better for both the veteran and the physician to create a medical organization that in the fullest sense appealed to the returning medical officer and to the recent medical graduate. The veterans' hospitals should indeed be comparable with modern, first-class, teaching institutions.

A bill (H R 4717) introduced by the Democratic leader, Mr. Rankin, and recently enacted into law by the signature of President Truman promises to do much to remedy existing conditions. It abolishes the medical service in the Veterans Administration as at present constituted and substitutes the Department of Medicine and Surgery which will establish a complete medical and hospital service, under the supervision of the Administrator of Veterans Affairs. There will be a medical director, a deputy medical director, eight assistant medical directors and a director of nursing. In addition, there would be a pharmacist, a dietitian, a physical therapist and an occupational therapist, as well as a dentist and an oral surgeon, each in charge of his particular division. The administrator, furthermore, has authority to establish residencies and to appoint qualified persons without regard to civil service or classification laws, rules or regulations, and there will be part-time consultants. For those in charge and all others employed, the specified salaries are fully adequate to attract a well trained personnel. In addition, a qualified specialist is entitled to 25 per cent additional pay, but no doctor shall be so rated unless he is a diplomate of his particular specialty board. Thus, it is apparent that the veterans should receive the best of medical and surgical care and that the positions available to physicians will be attractive, not only from the financial but also from the professional angle.

*Editorial: Medical care for veterans. *New Eng J Med* 233:196, 1945

tension and medial degeneration, which was quite severe

DR WHITE I think that he had a hypertensive aorta. The x-ray films did not establish the diagnosis of dissection, but often the root of the aorta is as prominent in hypertension as in syphilis. I think that most of the right-sided vascular shadow is aorta rather than pulmonary artery.

DR CASTLEMAN We did not find much blood in the dissected part of the aorta.

DR WHITE Once in a while that is the case.

DR CASTLEMAN I believe that we have had only two cases with actual thrombosis in the dissecting channel. Usually the aneurysm is empty or has a few shreds of post-mortem clot. It is only when there is a large thrombus in the aneurysm that it might be possible to see an enlarged shadow by x-ray.

DR WHITE This could be simply the x-ray picture of a hypertensive aorta. A negative finding does not rule out a dissecting aneurysm, whereas a positive finding may be helpful.

DR CASTLEMAN This medial degeneration of the wall of the aorta was first described by Erdheim^{3,4} and called by him "medionecrosis aortae idiopathica cystica," because occasionally the chromatropic degenerative material breaks down to form small cysts (Fig 1). This condition was described in this country for the first time by Dr Alan Moritz.⁵ He is here today and perhaps will comment on it.

DR ALAN R. MORITZ I believe that there is still skepticism in some quarters regarding the occurrence of cystic medial necrosis of the aorta independent of atherosclerosis. I am sure that such skepticism is unjustified. It is true, however, that minor and, from a functional standpoint, inconsequential cystic

medial changes are frequently seen both with and without intimal disease and that such changes should be extensive if they are to be held responsible for aortic rupture. In my experience aortic rupture due to cystic medial necrosis is likely to run a more rapidly fatal course than that due to atherosclerosis.

DR WHITE In our series,⁶ the reverse is true. Several days usually elapse before death.

DR MORITZ I have only seen ten or twelve cases of aortic rupture due to cystic medial necrosis, but I am sure that the majority of these patients died within minutes or, at the most, a few hours after the aorta gave way.

DR CASTLEMAN Our experience here is that in cases that have a dissecting aortic aneurysm the intimal tear has always been on the basis of medial necrosis, rather than being due to atheromatous ulceration. In fact, the intima is usually quite smooth in the region of the tear. In those cases in which dissection did originate from an arteriosclerotic ulceration, the dissection was very short and was an incidental autopsy finding, not having caused any clinical symptoms.

DR WHITE This man lived for four and a half days. Is that the average?

DR CASTLEMAN Yes.

tribed largely to greater awareness of the disease, which resulted in early diagnosis, better isolation and prompt treatment with antitoxin. After the rise of the Nazis, however, diphtheria began to increase in incidence and in severity, largely owing to the fact that immunization had not been practiced on any large scale.

During the period immediately preceding the outbreak of war, the countries neighboring on Germany were still having low diphtheria rates. So long as communications and the exchange of populations between Germany and her neighbors were still limited, the trends of diphtheria incidence remained the same in each of these countries. After the beginning of the war, however, Germany began to "export" diphtheria with her troops. The neighboring victims of German aggression were thus faced with a disease that had had a relatively low incidence for some time, during which a new generation of susceptibles had grown up because of the lack of effective programs of immunization. As a result, there was a tremendous increase in diphtheria in many of these countries at a time when it was almost impossible to apply effective countermeasures. The only country that did not share in this great increase of incidence was Hungary, in which an extensive immunization program had been practiced just prior to its occupation by Germany. This program paid dividends by holding the diphtheria rates to reasonably low levels, and the increase that did occur could be accounted for by changes in the population.

The number of cases of and deaths from diphtheria in the United States has shown a decline, with few remissions, since the beginning of this century, and there has been a steady and sharp drop since 1920. Immunization against this disease has been practiced only on a voluntary basis and in general has been quite spotty throughout the country. Without doubt, many American troops in Europe have become carriers of virulent diphtheria bacilli, irrespective of whether they have had the disease. Those who are yet to return will have had a greater exposure and will undoubtedly carry with them a greater volume of potential infection. To prevent any serious outbreak in this country it is

therefore urgent that efforts at extending immunization against diphtheria be redoubled.

An immune population is the best prevention against the occurrence of a diphtheria epidemic. The low incidence of diphtheria in this country in recent years has created a feeling of security that is totally unwarranted and that, in fact, may be the fuel on which an epidemic will feed unless the dampening effect of widespread immunization serves as an effective control. The facts that there has been a low incidence of the disease and that there are now a large number of susceptibles make the population particularly vulnerable, and an effective immunization program is essential.

MASSACHUSETTS MEDICAL SOCIETY

REVIEW LECTURE COURSE

The review lecture course for physicians in the Boston area that has been arranged by the Subcommittee on Postgraduate Medical Education of the Postwar Planning Committee, Massachusetts Medical Society, in co-operation with the Massachusetts Department of Public Health, will begin on February 18. The meetings will be held at Sanders Theater in Memorial Hall, Harvard University, Cambridge. These lectures, which are primarily designed for general practitioners and former medical officers, will review progress in medicine during the past four or five years. The speakers have been urged to present their subjects in a simple and direct manner and to emphasize diagnosis and treatment from the point of view of the physician in general practice.

All those who plan to attend but have not enrolled should do so immediately by either returning the post card recently forwarded to all physicians in Massachusetts or addressing a post card or letter directly to the Subcommittee on Postgraduate Medical Education, Massachusetts Medical Society, 8 Fenway, Boston 15.

The detailed program for the first four weeks of the course is as follows:

REVIEW LECTURE COURSE

February 18 INFECTIOUS DISEASES *Chairmen* Charles A. Janeway and Edwin H. Place

5:00-5:45 Differential Diagnosis and Treatment of Infections of the Throat and Larynx *Edwin H. Place*
physician-in-chief, South Department, Boston City Hospital, clinical professor of pediatrics, Tufts College Medical School

There is, perhaps, one unfortunate provision, namely, that which states, "Any person to be eligible for appointment in the Department of Medicine and Surgery must — (a) Be a citizen of the United States — (b) In the medical service — hold a degree of doctor of medicine or of doctor of osteopathy." In some states, such as Massachusetts, a doctor, whether osteopathic or regular,

must pass the same examination before he may practice, in others, there is a separate licensing board for each. In the latter an osteopathic physician may be licensed to practice even though he could probably never pass the regular examination. The possible dangers of the situation are obvious, yet the act expressly states that "doctors must be graduates of a university approved

by the Administrator [and] have completed an internship satisfactory to the Administrator." Any possible danger is thereby lessened, if not eliminated.

There is no doubt but that this act offers to the veteran the best of service and to the doctor a great opportunity. With General Omar Bradley at the helm, one may be sure that his associates and subordinates will be of the highest personal and professional caliber, for his record has shown that, although cautious and careful in his judgment, once he moves, he brooks no interference. That Congress and the President have approved this legislation deserves commendation from civilian and veteran and physician alike.

MASSACHUSETTS MEDICAL SOCIETY POSTWAR LOAN FUND

The Postwar Loan Fund has been set up, and all discharged medical officers who were members of the Massachusetts Medical Society in good standing at the time of their entry into the service may apply for loans from this fund. For further information apply to

630,000 cases were notified in 1943 in those European countries that were still reporting infectious diseases fairly well. When countries are included from which reports were not available or incomplete, it may be safely assumed that there were about 1,000,000 cases throughout Europe in that year. This means that there were about 50,000 deaths from diphtheria, and these occurred mainly in the younger age

groups. The epidemic increased in proportions in most of the countries during the past two years, along with other infectious diseases, probably owing to the shifting of populations, poor nutrition, the breakdown of public-health programs and many other causes. There was a high prevalence of diphtheria among the German soldiers, and the liberating forces of the United Nations shared in this

increasing incidence of diphtheria throughout the European Theater of Operations. The usual forms of diphtheria of the upper respiratory tract, as well as severe wound infections, were encountered among the American forces in North Africa and later in Italy and on the rest of the Continent, and the disease is now prevalent among occupation troops. There has been a high incidence of cardiac and neurologic complications.

Last winter, Dr. Knud Stowman,* chief of the Epidemiological Information Service of the United Nations Relief and Rehabilitation Administration, analyzed some of the salient epidemiologic features of the European outbreak. The results of his analysis may well serve as a stimulus to action aimed at the prevention of a similar resurgence of this disease in this hemisphere and particularly in this country.

As in most European countries, diphtheria morbidity and mortality in Germany showed a steady decline after the rise that accompanied the end of World War I. The downward trend has been as-

"DIPHTHERIA REBOUNDS"

RECENT reports from Europe indicate that diphtheria has assumed epidemic prevalence and that the disease now encountered there is particularly virulent, with a high case fatality. About

EXECUTIVE COMMITTEE OF THE COUNCIL

On January 9, 1946, the Executive Committee of the Council, on the recommendation of the Committee on Membership and representatives from the supervising censors, took the following actions

Allowed the following named fellows, applying for retirement and with all dues paid and in good standing, to retire under the provisions of Chapter I, Section 5, of the by-laws

Hunter, Norman M (Middlesex South), 98 Packard Street, Hudson

Overlander, J Eliot (Hampden), 167 Maple Street, Springfield

Quest, James F (Suffolk), 409 Marlboro Street, Boston
Victor, Agnes C (Worcester), P O Box 188, Worcester
Williamson, Cordelia I (Suffolk), 464 Huntington Avenue, Boston

Allowed the following named fellows, applying for resignation and with all dues paid and in good standing, to resign under the provisions of Chapter I, Section 7, of the by-laws

Beaulieu, Florence A (Hampden), Monson State Hospital, Palmer

Margulios, Benjamin (Hampden), Monson State Hospital, Palmer

Allowed the following named fellow to change his membership from one district society to another, without change of legal residence, under the provisions of Chapter III, Section 3, of the by-laws

Moore, Francis D, 371 Walnut Street, Brookline (office Boston) (Norfolk to Suffolk)

Reinstated the following named physicians, under the provisions of Chapter I, Section 10, of the by-laws, who had been deprived of fellowship for the nonpayment of dues, provided their arrears in dues at the time of deprivation both to the Massachusetts Medical Society and to their district societies, plus their dues for the year 1946 both to the Massachusetts Medical Society and to their district societies be sent to the treasurer of the Society

Hagerty, Harry J (Worcester), 14 Ekman Street, Worcester

Sullivan, Leo J (Bristol South), 379 Whipple Street, Fall River

Remitted the dues owed the Society for the year 1946 of the following named fellow, who is ill and completely incapacitated and has been completely incapacitated for the past seven or eight years, under the provisions of Chapter I, Section 6, of the by-laws

Kaufman, M F (Worcester), 79 Elm Street, Worcester

The personnel of the Committee on Membership is as follows Harlan F Newton, *chairman*, Roy V Baketel, William A R Chapin, Peirce H Leavitt, and Samuel N Vose The representatives of the supervising censors were as follows William H

Allen, H Quimby Gallupe, and Albert E Parkhurst

MICHAEL A TIGHE, M D, *Secretary*
Executive Committee

DEATHS

KEITH — Theodore K Keith, M D, of Newton Center, died January 15 He was in his forty-fourth year

Dr Keith received his degree from Boston University School of Medicine in 1926 In 1943 he entered the Army Medical Corps, serving overseas for two years in England, France and Germany

His widow, two sons, his mother and father and a brother and sister survive

LEE — Frank R Lee, M D, of North Andover, died October 15 He was in his forty-third year

Dr Lee received his degree from Tufts College Medical School in 1927 He was a fellow of the American Medical Association

ROBBINS — Fred G Robbins, M D, of Salem, died May 16 He was in his seventy-sixth year

Dr Robbins received his degree from Harvard Medical School in 1892

His widow survives

MISCELLANY

MACY FOUNDATION DISCONTINUES REPRINT SERVICE

Doctor Willard C Rappleye, president of the Josiah Macy, Jr, Foundation, announces that more than five million copies of over four hundred leading medical and scientific articles have been published by the Foundation's War Reprint Service during the last three years for medical officers of the armed forces of the United States and, in so far as possible, of Canada, England, New Zealand, Australia, the Union of Socialist Soviet Republics and China Dr Rappleye stated that, with the plans for demobilization of the armed forces, the service was discontinued on January 1

The War Reprint Service has been an effort to bring new and important developments in the science and practice of medicine to medical officers who were largely cut off from sources of medical information during the war In the selection of these articles the Foundation has had the active co-operation of the Committee on Pathology of the Division of Medical Sciences, National Research Council, and of the National Committee for Mental Hygiene The articles selected for reprint and distribution were those dealing with the most recent scientific developments that had a direct bearing on medical and health problems related to military service The distribution to the medical officers was worked out in co-operation with the surgeons general of the Army and Navy and the Air Surgeon Through the courtesy of the National Committee for Mental Hygiene, more than one million reprints were delivered to medical officers specializing in neuropsychiatry

In addition to the articles reproduced from journals the Foundation published for the Air Surgeon five original monographs, prepared by medical officers of the Army Air Forces, dealing with personality disturbances occurring in combat zones Over ninety-five thousand copies of these monographs were distributed by the War Reprint Service as official documents of the Office of the Air Surgeon Eight additional monographs and nine reviews of medical literature on subjects of military interest were also prepared, and seventy thousand copies were distributed Since August, 1944, a *News Letter* for the Rheumatic Fever and Streptococcus Control Program of the Army Air Forces has been published monthly for the Air Surgeon, and over one thousand copies each month have been mailed to interested medical officers, military hospitals and medical-school libraries With the help of the Interdepartmental Committee on Cultural and Scientific Co-operation of the Department of State, sixty

5 45-6 30 Poliomylitis Conrad Wesselhoeft physician-in-chief, Haynes Memorial, Massachusetts Memorial Hospitals, clinical professor of communicable diseases, Harvard Medical School and Boston University School of Medicine

7 30-8 15 Colds, Influenza and Pneumonia Maxwell Finland chief, Fourth Medical Service, and associate physician, Thorndike Memorial Laboratory, Boston City Hospital, assistant professor of medicine, Harvard Medical School

8 15-9 00 Progress Report Charles A Janeway assistant professor of pediatrics, Harvard Medical School, visiting physician, Children's Hospital, associate in medicine Peter Bent Brigham Hospital

February 20 CARDIOVASCULAR DISEASES *Chairmen* Herrman L Blumgart and Burton E Hamilton

3 00-3 45 Chronic Rheumatic Heart Disease Diagnosis and treatment Edward F Bland instructor in medicine, Harvard Medical School, visiting physician, House of the Good Samaritan, assistant visiting physician, Massachusetts General Hospital

3 45-4 30 Arterial Hypertension and Its Treatment Robert W Wilkins associate professor of medicine, Boston University School of Medicine, member, Evans Memorial, Massachusetts Memorial Hospitals

4 30-5 15 Electrocardiography in General Practice James M Faulkner professor of medicine, Tufts College Medical School

5 15-6 00 Treatment of Congestive Heart Failure Samuel A Levine assistant professor of medicine, Harvard Medical School, physician, Peter Bent Brigham Hospital

February 25 CARDIOVASCULAR DISEASES *Chairmen* Herrman L Blumgart and Burton E Hamilton

5 00-5 45 Neurocirculatory Asthenia and Functional Cardiovascular Disturbances Paul D White lecturer in medicine, Harvard Medical School, physician, Massachusetts General Hospital

THE REHABILITATION OF PATIENTS TOTALLY PARALYZED BELOW THE WAIST, WITH SPECIAL REFERENCE TO MAKING THEM AMBULATORY AND CAPABLE OF EARNING THEIR OWN LIVING*

II. Control of Urination

DONALD MUNRO, M.D.†

BOSTON

EVERY patient who has sustained an injury to the spinal cord, conus or cauda equina and is intelligent and co-operative has the right to expect infallible twenty-four-hour control of urination by the time he leaves his physician's care. Only those whose bladders have been denervated because of bilateral destruction of the parasympathetic plexuses or the lower four sacral segments or roots need any extraneous aid. Their numbers are negligible among civilians. Control of urination is an essential preliminary to self-support. No one will either walk abroad or be able to hold a job if he smells or if his clothes are wet with urine. There is no third choice between twenty-four-hour control with ambulation and self-support and a uriniferous aura with constant invalidism — usually in an institution — at the expense of the patient's family or the public.

It is the purpose of this paper to present evidence that therapy of the proper kind, properly applied with perseverance and patience over a sufficiently long time, will assure this end result to all such patients. No discussion of the details of the technique of treatment will be offered at this time. This will be considered by itself in a subsequent communication.

MATERIAL

One hundred and twenty-five patients have been selected for this study from a group of 243 with injury to the spinal cord, conus or cauda equina. Every segment of the cord from the fourth cervical to the tip of the conus and all parts of the cauda equina are represented. One hundred and one of these 125 patients were chosen, first, because they had lived long enough — that is, one month or more — after the injury to permit some conclusions to be drawn as to the efficacy of the therapy, second, because a sufficient number of cystometrographic observations were made to verify the actual physiologic

state of response of the bladder at frequent intervals, third, because all had become stabilized at an end point in so far as the genitourinary system was concerned. In addition 24 patients in whom tidal drainage was either not needed or not used are included for comparison.

Thirty-one patients had an injury of the cervical cord, 49 of the dorsolumbar cord and 9 of the sacral cord and conus, whereas in 36 the cauda equina was damaged (Table 1). The patients with an anatomic transection had a total sensory and motor paralysis below the level of injury, with a complete severance of the cord and total separation of the cut ends. Those with a physiologic or functional transection had a total sensory and motor paralysis below the level of injury, but a small vestige of neural tissue bridged the gap and the transection, although physiologically complete, was not anatomically so.

TREATMENT

Any treatment that leads to infallible twenty-four-hour control of micturition and meets the criteria listed at the opening of this paper must be considered satisfactory. I am not aware, however, of any procedure except tidal drainage that does this. Except where otherwise noted, this method was used as the fundamental therapy of the genitourinary tract in all cases reported herewith. Bladder stones, when present, were crushed intravesically. In the earlier cases, this was done without preliminary preparation. In the later ones, litholapaxy was postponed until after a period of bladder irrigation with Solution G.¹ Frequent intravenous and retrograde pyelograms were made as indicated. Originally a 1:30,000 solution of potassium permanganate was used as an irrigating fluid, but this was later changed to 0.5 per cent acetic acid, and in the last year or more this in turn has been discarded for either Solution M or Solution G.¹ Many other solutions have been tried but none of them compare in efficacy with acetic acid and the buffered

thousand reprints were distributed to medical teachers and investigators in forty-eight foreign countries. The Office of War Information requested permission to circulate the Foundation's reprints among more than thirty of their foreign outposts and reduplicated selected articles for their distribution to medical leaders abroad.

NOTICES

ANNOUNCEMENTS

Dr R Earle Glendy, having returned from service with the United States Army, announces the opening of his office at 820 South Jefferson Street, Roanoke, Virginia, for the practice of internal medicine, with special interest in diseases of the heart and circulation.

Dr Langdon Parsons, having returned from military service, is resuming the practice of surgery at 264 Beacon Street, Boston.

BOSTON MEDICAL HISTORY CLUB

There will be a meeting of the Boston Medical History Club in Sprague Hall at the Boston Medical Library, 8 Fenway, on Monday, February 11, at 8 15 p m. Dr Charles F Branch will speak on the subject "Some Aspects of the History of Cancer."

All interested persons are cordially invited to attend this meeting.

NEW ENGLAND SOCIETY OF PHYSICAL MEDICINE

The regular meeting of the New England Society of Physical Medicine will be held at the Hotel Kenmore, Boston, on Wednesday, February 20, at 8 p m. Dr David C Ditmore will speak on the subject "The Diagnosis and Treatment of Hemorrhoids, with Special Reference to Physical Medicine."

NEW ENGLAND HEART ASSOCIATION

The annual Henry Jackson Lecture under the auspices of the New England Heart Association will be given by Dr Tracy B Mallory at 8 15 p m on Tuesday, February 26, at the Boston Medical Library. His subject will be "Certain Features of the Pathology of Traumatic Shock."

Interested physicians and medical students are cordially invited to attend.

NEW ENGLAND PEDIATRIC SOCIETY

The annual meeting of the New England Pediatric Society will be held in Boston on Thursday, February 28.

HERMANN M BIGGS MEMORIAL LECTURE

The Hermann M Biggs Memorial Lecture under the auspices of the Committee on Public Health Relations, New York Academy of Medicine, will be delivered by Dr Laurence H Snyder, professor of medical genetics, Ohio State University, at 8 30 p m on Thursday, April 4, in Hosack Hall, New York Academy of Medicine. His subject will be "Medical Genetics and Public Health."

All persons interested are invited to attend.

ELLA SACHS PLOTZ FOUNDATION FOR THE ADVANCEMENT OF SCIENTIFIC INVESTIGATION

During the twenty-second year of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation, thirty-eight applications for grants were received by the Trustees, twenty-five of which came from the United States, the other thirteen coming from five different countries in Europe, Asia, North and South America. Twenty-two grants were distributed.

Applications for grants to be held during the year 1946-1947 must be in the hands of the Executive Committee before April 15, 1946. There are no formal application blanks but letters asking for aid must state definitely the qualifications of the investigator, an accurate description of the research, the size of the grant requested and the specific use of the money to be expended. In their requests for aid applicants should state whether or not they have approached other foundations for financial assistance and what other sources of support are relied on for research. It is highly desirable to include letters of recommendation from the directors of the departments in which the work is to be done. Only applications complying with the above conditions will be considered. Applications should be sent to Dr Joseph C Aub, Massachusetts General Hospital, Fruit Street, Boston 14.

reflex level, depending on the type of cord injury, cystometrograms should be done at least once a week, and oftener if indicated. Only in this way can the physician so adjust his therapy as to suit it to the needs of the particular bladder under treat-

cystometrograms and further simplifies collecting the required observations.

Tidal drainage as a therapeutic procedure has also been criticized as needing a specially trained technician to operate it efficiently, as requiring such constant attention as to necessitate extra ward personnel—especially at night—and as causing necrosis of the bladder.⁹ It is a matter of record that the system has been effectively used in China (Fig 3), in various clinics in the United States,¹⁰⁻¹⁴ England,^{5, 15-18} Canada,^{7, 19} and Mexico,²⁰ in American Army hospitals in this country²¹⁻²⁵ and in England²⁶ and on islands in the South Pacific. It has also been used on airplanes and on vessels during transatlantic crossings.²⁷ Lowsley and Kirwin,¹² Swartz,¹⁹ McLellan,¹⁰ Cone and Bridgers,⁷

FIGURE 1 The Tidal-Drainage Apparatus as Modified by McNeil and Bowler⁵ and O. W. Stewart⁶ (with built-in cystometer)

ment, and only thus can tidal drainage or any other equally effective method of treatment operate efficiently and act as a therapeutic agent.

Criticism of the use of tidal drainage in cord-injury cases has been made because of this need. It has been said that it is not worth while and that it takes too much time to go to all this trouble to make so many observations. In the final analysis, this is a matter of the amount of interest the physician has in taking the necessary steps to see that his patient gets the best possible functional end result. Failure to employ all possible means for this purpose is a criticism not of any therapeutic procedure but of the physician performing it. The modern tidal-drainage apparatus (Figs 1 and 2),^{7, 8} which has a built-in cystometer, obviates the need for setting up a special apparatus for making the

FIGURE 2 The Tidal-Drainage Apparatus as Modified by Cone and Bridgers⁷ (with built-in cystometer)

McCrea,¹³ Thomas¹⁴ and the United States Army,^{21, 24-26} in this country and Canada, as well as Robinson,¹⁶ Stewart,⁶ Kerr,¹⁷ Wells¹⁵ and others in England and elsewhere, have written describing its successful use. In this clinic, medical students, interns within a year of graduation from

citric acid solutions, and of these the latter are far and away the better. The only complication that has followed their use has been an occasional scrotal dermatitis when too much leakage around the catheter or lack of cleanliness has been permitted. In the male, a No 16 or 18 Fr soft-rubber rectal tube, held in place with adhesive-tape strapping around the penis, and in the female, either a similar rectal tube taped to the pubis or a perforated mushroom-tipped soft-rubber catheter of the same size have been used almost without exception as catheters. A Foley-type catheter has been used only rarely and has never been considered essential. The catheters have been removed, cleaned and resterilized, and replaced or a new one has been substituted once a week, at which time a urine culture² has been made. For the last six years no drugs

present was cured or brought under control before attempting to start the training period. Culturable bacteriuria has been constantly present so long as the catheter was in use,² but it has disappeared in almost every patient and regardless of the kind of infecting bacteria following removal of the catheter and without the use of medication when either normal micturition has been established or the training period has been completed. Any operation, exhaustion, impairment of nutrition, anemia, concurrent infectious disease or surgical infection anywhere in the body causes the bladder function to regress, even to the point of becoming atonic if normal micturition has not already been re-established. Conversely, good general health and nutrition and in particular a normal blood content and circulation, together with physical activity and

have been employed to sterilize the urine. In the earlier cases many different ones were tried by mouth, intravenously and in solution for use in the bladder, but none of them produced any effect. The fluid intake is kept at 4500 cc every twenty-four hours for adults with a normal circulation. This amount is scaled down to an appropriate level for children and cardiac invalids. As soon as the activity of the bladder becomes established at a reflex level, a period of training in bladder control is begun. In patients with a transection, this produces sufficient bladder capacity so that they can go a minimum of three hours during the day and while active, and the entire night without wetting themselves or being awakened. The bladder nevertheless continues to function on the "reflex" as opposed to the "normal" level.³ In nontransecting injuries a normal bladder results. Except in cases with a destructive lesion of the sacral cord, with a resultant denervation of the bladder, all patients, regardless of the original injury, have had either a normal or a reflex bladder at discharge and have been free of catheters and any form of urinal, as well as of the need for using tidal drainage. Contracted or shrunken bladders have been stretched to a capacity of 200 cc before reflex emptying. Any cystitis or pyelitis that was

exercise within the limits of the patient's capacity, facilitate progress toward normalcy and controlled reflex micturition. Experience has demonstrated that aside from intelligent co-operation on the part of the patient during the training period, the two most important factors in attaining a satisfactory end result are a knowledge at all times of the functional stage that the bladder has reached in its progress toward either complete recovery or a reflex level and the need for instituting therapy by tidal drainage at the earliest possible moment and preferably at once after receipt of the injury. The first is possible only if frequent cystometrograms⁴ are made. The initial one should be made when the patient is first seen or as soon thereafter as possible. It is no more reasonable to expect to treat a case of surgical shock or circulatory collapse, for example, without a blood-pressure reading at the first visit than it is to treat the bladder of a patient with a spinal cord injury without a cystometrogram at the earliest possible moment. The function of the bladder can not be estimated without a cystometer any better than the state of the circulation can be judged without a sphygmomanometer. This analogy is equally true in the later stages. Until the bladder function has been stabilized at either the normal or the

COMPLICATIONS

The complications relative to the bladder the urethra and the paraurethral structures that developed in this series have been analyzed in relation to their presence at the time of admission in patients in whom tidal drainage was either not begun for an appreciable interval after the receipt of the injury, was not needed or was not used when it should have been and in relation to their recur-

vaginal fistula. A vasectomy was performed on 1 patient. Thus, 26 per cent had complications already present before tidal drainage was started. By comparison, of the 52 patients treated with tidal drainage from the receipt of the injury, 3 had bladder stones, 4 urethritis, 1 a periurethral abscess, 1 prostatitis, and 2 epididymitis. One patient had a vasectomy. Thus, 23 per cent had complications traceable to the therapy. It is worth noting, however, that in 26 patients, 11 of whom had transec-

rence during treatment by this method. It has proved impossible to determine accurately the presence or absence of pyelitis and its relation to the use of this therapy, and this complication is therefore not included. It can be definitely stated, however, that all the patients who had pyelitis during their hospital stay were free of it at the time of discharge. One patient in whom tidal drainage was begun after an interval and one who was not

tions, who have come under treatment in the last six years the only complications have been bladder stones in the 3 cases just mentioned and urethritis and prostatitis in 1 case each. It has only been since the commencement of this period that the apparatus and the technic of managing it have reached a high level of efficiency. The percentage of complications in this group was 19. It is probable that this incidence can be lowered still further now

treated at any time by this method each had a stone in one kidney. The stones were removed by appropriate surgery. Of the 65 patients in whom complications were present before tidal drainage was used or in whom it was decided not to employ it 6 had bladder stones, 4 a periurethral abscess, 3 epididymitis, 1 a dilated urethra, and 1 a vesico-

that the development of bladder stones appears to be reduced to a minimum by the use of the buffered citric acid solutions (Solutions M and G).

OTHER METHODS OF TREATMENT

A number of other methods of treating the bladder in patients with injury to the spinal cord, conus

medical school and nurses have all learned to set it up and supervise the operation with a week or ten days' training and with no more supervision than is required for any other ordinary procedure in a surgical ward. No personnel beyond the single nurse on duty at night or the usual ward staff at any other time has ever been required to care for anywhere from three to twelve patients being treated simultaneously in this way. Any trouble

autopsy when tidal drainage has been previously used nor at cystoscopy, nor has it been suggested by any clinical symptoms in the surviving patients. In the face of such experience and in the absence of details in support of their claim, this statement made by Barrington, Everidge and Morson must be disregarded, and any other conclusions drawn by them on this subject must be looked at with suspicion.

Objection has also been raised to the use of tidal drainage because an inlying catheter is necessary. It is claimed^{9, 18, 23, 25, 28} that the presence of a catheter in the urethra for any appreciable time causes urethritis, epididymitis, periurethral abscesses, necrosis of the mucous membrane, strictures and so forth. It is generally agreed that the urethra is constantly contaminated and that the complications listed above are primarily the results of pressure necrosis from the catheter, with subsequent infection of the dead tissue. Interference with the drainage of the normal urethral secretions is a contributory cause. Despite this fact, a large catheter that completely fills the urethra is frequently used in males with the object of controlling leakage from the bladder. I am convinced that urethral complications only follow the use of a catheter that is *too large* or that has been inserted with the aid of a stylette (Table 2). Leakage of urine around the catheter depends not on the size of the tubing but rather on the integrity of the sphincters that surround and compress it. When closed, such sphincters assure retention of the urine in the bladder no matter what the size of the catheter that passes through them, but when they are open, leakage is inevitable despite all attempts to plug the bladder. I am certain that it is neither necessary nor good practice to use an inlying catheter larger than No. 16 or 18 Fr. If this rule is adhered to and the catheter is removed, cleaned, resterilized and reinserted in a sterile manner once a week, no urethral or periurethral complications such as those listed above will develop.

The importance of beginning tidal-drainage treatment early if complications are to be avoided and a satisfactory end result reached is apparent from Table 3. In particular, it should be noted that whereas the genitourinary tract was infected in 98 per cent of the cases at the beginning of tidal drainage, when use of the latter was delayed until some time after the receipt of the accident, only 8 per cent were similarly infected when it was used from the first. Although 12 patients (24 per cent) developed infection of the genitourinary tract while being treated with tidal drainage, infection was present in only 8 per cent of this group at discharge, in contrast to 20 per cent in the other group and 17 per cent in the patients that had no such therapy at any time. Sixty-nine per cent of the first group had no infection at any time. That this therapy was efficient is evidenced by these figures.

脊髓膀胱 (Cord bladder) 之治療

張宗華 葉枚霖

脊髓膀胱之初期，人既衰弱而呈過度膨脹之現象，如醫治不得其法，則膀胱漸形膨脹，自一九三四年孟氏(Munro)將連續灌流法(Tidal drainage)應用於脊髓膀胱醫治之後，上述症狀既可預防，又膀胱之發炎，可以減少，而石蓋病人，亦較便利，膀胱癌亦不易發生。據孟氏個人四年之經驗，該項病症之死亡率，可減至百分之十。強尼連灌流法之於脊髓膀胱之治療，有顯著之功效。連續灌流法之應用，須先對於各型之脊髓膀胱有詳細之認識。

501

FIGURE 3

that has arisen has been traceable at all times to improper adjustment of the apparatus to the bladder that it was serving.

The criticism that this apparatus causes gangrene of the bladder, made by Barrington, Everidge and Morson,⁹ merits more serious attention. This occurred in the course of a joint meeting of the sections of Urology and Neurology of the Royal Society of Medicine. Nothing beyond the bold statement appears to substantiate this claim. No one else, so far as I am aware, has made a similar statement, and none of the other speakers on the same program are reported to have made such a criticism. These authors made no mention of the number or type of cases that developed gangrene and were treated with tidal drainage or in any other way. No suspicion of such a complication has ever arisen in any of my 101 patients nor in any others who were similarly treated in this clinic for less than a month. The condition has never been found at

not use absorptive pads around the tube and is not constantly faced with the choice of disposing of damp or wet pads or smelling of stale urine. There is the further consideration that an inlying suprapubic tube causes pain when the body is in certain positions and thus limits physical activity, is prone to rot and break in two leaving a free foreign body in the bladder, serves as a source of irritation, infection and stone formation fails to prevent puddling, with consequent infection of the genitourinary tract, anchors the bladder abnormally

FIGURE 4 Roentgenogram of a Dilated Urethra, with Looping and Kinking of the Catheter in the Dilated Portion. This patient had an anatomic transection of the thoracic cord and had been using a penile clamp for one month.

to the abdominal wall, and promotes shrinkage and fibrosis of the bladder wall with a progressive decrease in capacity and consequent increasing uselessness of the organ as a reservoir.

The only justification for this operation as a means of treating the bladders of patients with injury to the spinal cord or cauda equina lies in the circumstances that surround combat conditions in war and the difficulties of transport that go with them. It may well be impossible to provide sufficient supervision to maintain proper catheter drainage under such conditions. Because this is essential, the lesser risk of draining the bladder suprapubically rather than by the preferable route through the urethra must be taken to avoid the greater risk of no drainage

at all. There is no reason why it should be necessary to employ it, however, except in these or analogous circumstances. If it has been used, steps should be taken to close the fistula at the earliest possible moment. This should not be undertaken, however, until after cystoscopic examination with intravenous and if necessary retrograde pyelography and a study of specimens of urine from the kidney pelvis have eliminated the presence of stones anywhere in the genitourinary tract, major pyelitis or pyelonephritis, encrusting or ulcerative cystitis and an occluded urethra. If such conditions exist, appropriate operative treatment of the kidney and intermittent manual irrigation of the bladder with Solution G should be carried out, and restoration of the urethral patency should be established before closing the fistula.

Such irrigation has been most effective in my hands when the fluid enters the bladder by way of an inlying urethral catheter, with the suprapubic tube kept closed until leakage takes place around the latter. In this way a maximum amount of the irrigating solution is introduced into the bladder, and at the same time the bladder wall is gently stretched and its capacity is gradually increased. Between irrigations the bladder should be allowed to drain through the catheter and not through the suprapubic opening. After these preliminaries have been completed, the suprapubic fistula can be closed.

It is undoubtedly true that almost all such fistulas eventually close spontaneously after removal of the suprapubic tube and without further local therapy, and it is customary to allow them to do so. This seems to be an extremely unsurgical method of dealing with this problem. The trouble that is saved by permitting closure in this way rather than by resorting to surgical closure with excision of the fistulous tract and surrounding scar does not justify the restriction of bladder activity that must be associated with the former method and that is reduced to a minimum by the latter one. So long as the fistulous tract is present the bladder will be anchored to the abdominal wall, which is neither anatomically nor physiologically correct.

In the group of patients under discussion, the bladder, even under the best of circumstances, works under a tremendous handicap. The more nearly perfect its anatomic and physiologic relations to the surrounding tissues, the nearer is its approach to normal function. A surgical closure and excision of the fistula and scar, with layer sutures of the bladder and overlying tissues and appropriate post-operative drainage of the space of Retzius, leaves a minimal amount of perivesical scarring and adhesion and permits maximal mobility of the bladder in the course of filling and consequent maximal storage capacity. Overstretching of the wound and leakage through the surgical incision can be prevented by constant urethral drainage during wound

or cauda equina have been advocated. I have been unable to find that any advocate of these alternative methods has claimed infallible twenty-four-hour control of urination as the result of their use. Even in clinics in which tidal drainage has been used,^{6, 7, 10, 11, 15, 17, 19, 21, 22, 26} I am not aware of any published results in, for example, patients with transected cords that offer any better genitourinary end result than a so-called "automatic bladder." Such a bladder is in fact, and as evidenced by cystometric studies, a reflex bladder.⁸ Instead of the patient's being given infallible twenty-four-hour control of micturition without the aid of apparatus, dryness and safety are secured only with the help of urinals and pads, and a night's sleep only at the cost of dangerous reduction of the fluid intake with consequent risk of pyelitis, or, when accompanied by a wet bed, frequent waking, the discomfort of rubber sheets, inability to spend a night away from home and the like.

The perennial argument whether it is better, particularly in the early stages, to permit the bladders of patients with injury to the cord or cauda equina to overflow or to empty them periodically by intermittent catheterization or by manual expression of their contents stems from ignorance of the processes by which a bladder that has been so paralyzed recovers. Automaticity is the best that can be expected from such treatment, and this can be gained only at the risk of permanent damage to the bladder wall and major infection of the genitourinary tract. This subject has been well covered elsewhere,^{3, 16, 29, 30} and the discussion need not be repeated here. Proper cystometric investigation will demonstrate that none of these three methods are appropriate and that all are dangerous. If the patient is so fortunate as to acquire an "automatic bladder" this same lack of knowledge deprives him of an ideal end result, only because his physician fails to afford him the opportunity for the final training that makes the difference between a complete functional success and a makeshift near-failure.

Intermittent Irrigation

Manually controlled intermittent irrigation used alone leads at best only to an "automatic" or reflex bladder. This method has been described by Low-ley and Kirwin¹² and advised, among others, by the Medical Department of the United States Army.²⁴ There is no question that this method when properly used by an intelligent patient and under the direction of a careful and competent physician is the best substitute for tidal drainage. It will, without doubt, permit the development of a reflex bladder without infection of the genitourinary tract in an unknown percentage of patients with injury to the cord or cauda equina. It cannot be denied, however, that it is inaccurate, time-consuming, unphysiologic and relatively ineffective

unless checked by frequent cystometric observations. A period of bladder training must follow its employment if practical useful urinary control is to be expected. I have personal knowledge of two clinics in which this method was used. In one it was a brilliant success, and in the other it was a dismal failure. The difference in results was directly traceable to the efficiency of the physicians in charge. The automatic feature of tidal drainage does away with this hazard. Next to tidal drainage, however, manually controlled intermittent irrigation appears to be the most satisfactory therapy for the cord bladder, and if properly handled and followed by bladder training it can be used instead of it.

Penile Clamp

The simplest method of urinary control in males is that associated with the use of a penile clamp. Urinary leakage can unquestionably be prevented by this means, but only at the expense of a possible dilated urethra in cases of cord injury. Whenever a reflex bladder has been established, an emptying contraction of the detrusor muscle, with associated relaxation of the internal and external sphincters, develops in response to a critical amount of stretch of the bladder wall. If a mass reflex is present, the bladder may also empty at any time and regardless of the amount of fill.³¹ Once such a contraction starts, it continues until either the bladder is emptied or the detrusor is exhausted and again relaxed because of its inability to overcome an external resistance that is greater than the force of its contraction. It is this latter condition that accompanies the use of a penile clamp. The forceful expulsion of the urine from the bladder into the urethra up to the point of compression by the clamp dilates the urethra (Fig. 4) and bladder and causes puddling of the bladder urine, with cystitis and attacks of pyelitis as inevitable consequences. This can only be avoided by release of the clamp whenever such an emptying contraction occurs. Such a regimen predicates a knowledge of bladder training as referred to above and the abolition of the mass reflex when necessary.³¹ Under such circumstances, a penile clamp is superfluous. Its employment is justified, therefore, only in exceptional circumstances, and then merely as insurance against failure on the part of the patient to urinate at regular intervals and in the absence of a mass reflex.

Suprapubic Cystostomy

Suprapubic cystostomy both as a temporary and as a permanent method of treating cord bladders has many advocates. Its use as a permanent method in cases of cord injury cases appears to be illogical and indefensible. Surgeons claim that when the cystostomy is properly performed the bladder does not leak. I have yet to see a patient with a cord injury whose bladder has been drained in this way who will agree with this statement or who does

uch factors as associated sepsis, hypoproteinemia, early death, mental changes, lack of co-operation and concomitant disease, all conditions that had no direct connection with the therapy. Only 5 cases of failure (5 per cent) are attributable to the use of tidal drainage. Four of these were in early patients who were cared for while the apparatus was still being developed, they can also be eliminated from consideration. It may be concluded, then, that only 1 of 101 patients (0.9 per cent) with an injury to the spinal cord or cauda equina who

the spinal cord, conus or cauda equina and is intelligent and co-operative can have infallible twenty-four-hour control of urination by the time he leaves his doctor's care.

If tidal drainage is used at once after receipt of the injury and supplemented by frequent cystometrograms, the chance of obtaining this result is 20 per cent greater than if its use is delayed.

In a series of 101 cases selected from a larger group of 243 patients with injury to the spinal cord, conus or cauda equina, only 1 patient (0.9 per cent)

had had effective therapy, were free of associated infection, were neither senile, feeble minded nor psychopathic, would co-operate and were not still under treatment failed to have twenty-four-hour control of urination at the time of discharge. This end result was obtained only because of the efficient use of tidal drainage. The chances of securing this result were somewhat better (70 as opposed to 50 per cent) when tidal-drainage therapy was begun at the earliest possible moment after the injury. Transection of the cord below the first thoracic segment, whether anatomic or physiologic, does not of itself deprive the patient of this end result.

SUMMARY

Evidence is presented in support of the contention that every patient who has sustained an injury to

in whom tidal drainage was properly used for a sufficient length of time failed to have infallible twenty-four-hour control of urination at the time of discharge.

I am indebted to Dr. Augustus Riley, consulting surgeon for urology, Boston City Hospital, for his assistance with this work, much of which would have been impossible without his co-operation.

healing and for a period of two weeks thereafter. At the end of this time tidal drainage can be begun, the bladder stretched to a useful capacity, and bladder training commenced in patients with transected cords after the bladder activity has become reflex or automatic. With such a background, neither the surgeon nor the patient need fear later suprapubic rupture when the bladder becomes distended.

Perineal Urethrostomy

Perineal urethrostomy need only be mentioned to be condemned. Its only advantage over suprapubic cystostomy is maintenance of drainage through the vesical sphincters. It accomplishes no more than does catheter drainage through the urethra and is as difficult to maintain under stress and with a shortage of attendants. In addition, it has all the risks that go with an open perineal wound. If it is maintained until the patient is ac-

The apparatus is difficult to clean, leaks develop easily in it, when full or nearly so it may overflow when the patient sits down, and it is useless when the patient is in bed. If the bladder is allowed to drain into it constantly, the critical level of fill, when associated with emptying of the reflex or "automatic" type, tends to decrease gradually until the bladder has so little capacity as to be useless as a reservoir. This is doubly true if the bladder is autonomic because of denervation. Proper bladder training in patients with a transected cord, supplemented in special instances by the use of a penile clamp and an inlying urethral catheter, with bladder irrigation at night by tidal drainage, will do all and more than a rubber urinal will do.

RESULTS

The results of treatment by tidal drainage as outlined above are summarized in Table 4. They are

tive, moreover, the tract is sealed off whenever the patient is seated.

Rubber Urinals

It is possible for a patient with injury to the spinal cord or cauda equina to remain dry and control the urinary outflow while active by wearing a rubber urinal strapped to his leg, provided that all the circumstances are favorable and that he is willing to sacrifice his bladder as a reservoir and to regard it only as a passageway for urinary flow between the ureters and urethra. Women will not wear these devices, however, because they are not consistently leakproof, and prefer absorbent pads. When worn by men they must fit exactly around the penis if they are not to leak. Since they are manufactured only in two sizes, — one for adults and one for children, — the matter of fit depends purely on chance. If it happens that a patient is able to fit himself properly, he must be prepared to forego the use of the urinal whenever edema of the perineal or penile skin develops and alters the fit. Inasmuch as irritation caused by the constant immersion of the penis in the fumes of stale urine during periods of activity is inevitable, the usefulness and efficiency of the apparatus proves to be considerably below the level envisioned by the patient and his physician at the time of its purchase.

given in terms of twenty-four-hour control of urination at the time of discharge from the clinic. Seven of the 9 patients who have control at home with the aid of tidal drainage are early cases, and today would be trained to do without this aid. The other 2 patients have denervated bladders and must use it. All 9 wear catheters constantly and have learned to clean and sterilize them and the apparatus and to remove and replace the catheter once a week in a sterile manner. One woman has been doing this for over nine years and has come to no harm. At night the patients attach their catheters to the tidal drainage setup, but during the day they are free of the apparatus and go about with the catheter clamped off, opening it only to allow the bladder to drain at three-hour or four-hour intervals. Three of these patients were subjected to an anterior dorsolumbar rhizotomy for the relief of a mass reflex,³¹ 2 being the first ones on whom this operation was performed. Three others had functional transections, 1 had a demyelination of the cauda equina, and 2 have denervated bladders. Thus, 61 of 101 patients, including 38 with transections of the cord, have complete twenty-four-hour urinary control. Thirty-five have no control, and 5 are still under treatment.

Table 5 demonstrates that in 35 patients failure to attain twenty-four-hour control was caused by

The series consists of 21 cases of portal cirrhosis, with an additional case of possible arsenical cirrhosis as contrasted with so-called "alcoholic cirrhosis," 1 case of biliary cirrhosis and 2 cases of catarrhal jaundice in the acute phase (Table 1). Four pentoneoscopies, with biopsies in 3 cases, and a post-mortem examination have substantiated the clinical diagnoses. Four of the patients have died —

afebrile after treatment for specific infections. One patient (Case 7), in whom hemolytic *Staphylococcus aureus* was cultured from both the blood stream and the ascitic fluid, was treated with penicillin. Three patients (Cases 10, 11 and 15) were treated with sulfonamides for pneumonia.

Twenty-four patients showed no urinary sugar in the routine qualitative Benedict tests done on

1 of bronchopneumonia, 1 of cardiac failure and 2 of hemorrhage from ruptured esophageal varices.

CLINICAL EVIDENCE OF LIVER DISEASE

Of the 25 patients studied, 15 gave histories of markedly elevated alcoholic intake, 8 were moderate drinkers, and 2 denied any use of alcoholic beverages. Thirteen patients gave dietary histories of food intake adequate in vitamin content as well as in caloric value.

The general nutritional status of these patients at the time the tests were performed was judged as good in 11 cases, fair in 4 and poor in 10. No patient, however, showed either marked obesity or emaciation.

Thirteen patients had occasional low-grade fever during hospitalization, 8 were afebrile, and 4 became

morning specimens. One (Case 11) frequently had a + to ++ test for sugar in the morning urine.

The significant physical and laboratory findings that were of aid in the general analysis of the extent and severity of the liver damage found in these cases are included in Tables 2 and 3. For purposes of tabulation, the various findings have been graded from 0 to ++++ to indicate the degree of abnormality found.

Hepatomegaly was demonstrated by palpation in all but 3 cases, and in these the ascites was so marked that adequate examination of the abdomen was impossible (Table 2). Palpable spleens were demonstrated in 7 cases. For both the liver and the spleen the degree of enlargement roughly corresponded to the number of fingerbreadths that the organ extended below the costal margin. Seventeen pa-

THE INTRAVENOUS GLUCOSE - TOLERANCE TEST IN LIVER DISEASE*

JAMES A CAMPBELL, M D,† AND HENRY J TAGNON, M D ‡

BOSTON

THE liver plays an important role in the metabolism of carbohydrates. Clinical investigators have frequently reported observations of disturbed carbohydrate metabolism in the presence of liver disease,¹⁻⁶ and numerous studies have been made of the metabolic alterations found in experimental animals with liver damage induced either by toxic agents or by partial or total hepatectomy.⁷⁻⁹

The possibility that alteration of liver function enters into the production of the diabetic syndrome has been considered by many authors, and several reports have been published that emphasize the possible role of the liver in the etiology and pathogenesis of diabetes mellitus in human beings.

In 1939, Conn and Newburgh,¹⁰ in an amplification of an earlier work,¹¹ reported their observations of glucose-tolerance curves in a series of obese patients. A majority of these patients were found to have curves of the so-called "diabetic type" following the oral administration of dextrose, and these were attributed to the excessive accumulation of fat in the liver. Conn et al.¹² and Collier and his co-workers^{13, 14} reported the occurrence of such curves in patients with ascending infectious hepatitis. In their opinion, this abnormality was attributable to liver damage, and they reported a reversal of the abnormal curves to normal following

surgical treatment. In the above series, the tolerance curves were determined following the oral administration of glucose.

Soskin^{15, 16} has repeatedly emphasized the role of the liver in the pathogenesis of diabetes mellitus both in experimental animals and in human beings. In 1935, he and Mirsky¹⁷ observed abnormal oral glucose-tolerance curves of the diabetic type in certain patients with liver disease. Recently he and his co-workers¹⁸ reported the cases of 6 diabetic patients whose conditions were aggravated by biliary infection. In 1943, he¹⁹ published a preliminary report on abnormal curves obtained through intravenous dextrose-tolerance tests in patients with mild or early liver disease.

Many investigators have used oral glucose tolerance tests as a measure of liver function and have reported varying results.²⁰⁻²² The work reported herein was done in an attempt to determine whether there is an abnormality in carbohydrate metabolism as measured by an intravenous glucose-tolerance test, in patients with severe liver disease and to determine whether this procedure is a valid test of liver function.

METHODS

The 25 cases from which the data in this report were obtained were studied as they appeared in the wards of the Boston City Hospital, with no attempt either to include or to exclude patients with diabetic tendencies. The only criterion for selection was clinical and laboratory evidence of marked liver damage at the time the glucose-tolerance tests were performed.

*From the Thorndike Memorial Laboratory the Second and Fourth (Harvard) Medical Services Boston City Hospital and the Department of Medicine, Harvard Medical School.

The expenses of this investigation were defrayed, in part, by a grant given by the Ella Sachs Plotz Foundation in recognition of Dr. Francis W. Peabody's services to the Foundation.

†Teaching fellow in medicine, Harvard Medical School resident, Fourth Medical Service Boston City Hospital.

‡Instructor and Francis Weld Peabody Fellow in Medicine, Harvard Medical School tutor in biochemical sciences Harvard University assistant in medicine Boston City Hospital.

and Maddock²⁶ All such tests are standard procedures. The normal range of values, as well as differences to the method used in the various determinations, are included in the table.

Gradation of the extent of liver damage as shown by the liver-function tests was from 0 to + + + +. If 80 per cent or more of the tests performed gave abnormal results, the case was graded as + + + +,

obtained by them has been incorporated in Figure 1. In the same report they tabulated observations in a number of patients with known or suspected disease. The findings in the present study are consistent with those reported in Lozner's series for a group of 7 patients with liver disease.

To be considered abnormal, a value should differ from the normal mean value by an amount greater

FIGURE 1 Intra-venous Glucose-Tolerance Curve in Liver Disease

if 65 to 80 per cent of the tests did so, it was graded + + +, and if 45 to 65 per cent did so, it was graded as + +.

In addition, an intravenous glucose-tolerance test as described by Lozner, Winkler, Taylor and Peters³⁷ in 1941 was carried out in these patients. Urine samples collected during the test were analyzed for glucose by the quantitative method of Benedict.³⁵

A total evaluation of the severity of the liver disease was determined by consideration of the clinical findings, the laboratory evidence of abnormal liver function and the course. The disease was considered moderate in 5 cases, marked in 1, and severe in 19. No mild cases were encountered.

RESULTS

The original data are presented in Table 1. The form of the curve derived from these data relating blood-glucose values to time is indicated by the heavy black line in Figure 1. The individual curves varied considerably, but the average curve fell within the range in normal subjects. There were marked differences in blood-glucose levels at each of the three time intervals, with the least degree of variation, as well as the minimum standard deviation, occurring at the two-hour interval (Table 4). This is in accord with the findings in 60 normal subjects on whom this test was performed by Lozner and his co-workers,³⁷ and an analysis of the curves

than three times the standard deviation of the mean.

For further analysis of the results obtained in the present study, the cases were divided into the following groups, as suggested by Lozner et al.³⁷ Group A, those with blood-sugar concentrations, two hours after the injection, within the normal range, from 65 to 99 mg per 100 cc, Group B, those with moderate elevation of the blood sugar, ranging between 100 and 119 mg, Group C, those with markedly elevated blood sugar, ranging between

TABLE 4 Summary of Results of Intra-venous Glucose-Tolerance Tests

BLOOD SPECIMEN	BLOOD-GLUCOSE LEVELS			
	MAXIMUM	MINIMUM	ARITHMETICAL MEAN	STANDARD DEVIATION
	mg/100 cc	mg/100 cc	mg/100 cc	mg/100 cc
Fasting	132.0	42.5	81.2	20.1
One hour after injection	192.0	71.0	129.2	25.4
Two hours after injection	124.5	61.1	85.7	18.9

120 and 160 mg, and Group D, those with the blood sugar moderately depressed, ranging from 38 to 64 mg. The values in Group A differ from the normal mean established by Lozner by less than three times its standard deviation; those in Group B by more than three but less than six times, and those in Group C by more than six times. The results are presented in Table 5.

Four cases (Cases 7, 8, 19 and 21) were placed in Group B. Three of these were cases of portal

tients had ascites, and in 13 of these paracenteses were performed. The cases in which repeated taps were necessary or in which 5000 cc or more of fluid was withdrawn were graded as ++++. Those re-

significance has been assigned by some physicians,² were found in 11 cases. A grade of + + + +, indicating the extent of development of collateral circulation found in chroa-

cirrhosis, 2 of them with severe liver damage. None of the individual curves were remarkable in contour, however, or suggestive of the diabetic type of curve.

Two cases (Cases 11 and 16) were placed in Group C. Both patients had portal cirrhosis, one with severe and the other with moderate liver damage.

Included in the cases with moderate depression in the blood-sugar concentration are 3 of cirrhosis of the portal type and the single case of biliary cirrhosis in the series. By far the greatest portion of the cases with liver disease, however, were in the

TABLE 5 *Analysis of Distribution of Cases according to Blood-Glucose Levels in Fasting Specimens and Those Taken Two Hours after the Injection of Glucose*

GROUP	BLOOD-SUGAR LEVEL	
	FASTING	AFTER INJECTION
A (normal)	17	15
B (moderately elevated)	3	4
C (markedly elevated)	1	2
D (moderately depressed)	4	4

group showing normal blood-sugar values, both in the fasting state and two hours after the test glucose injection. This group includes 1 case of severe acute hepatitis, in addition to the cases of chronic liver disease.

Of Lozner's group of 60 normal persons, all except 1 showed glycosuria during the intravenous glucose-tolerance test, with a maximum amount of glucose excreted by any subject of 2.25 gm. In the present study, the patients exhibited glycosuria during the test in all cases except 2. The maximum total urinary glucose excreted in any one case was 2.50 gm, with an average total of 0.67 gm, showing no appreciable deviation from the normal.

DISCUSSION

Newburgh and Conn,^{10, 11} in discussing their observation of diabetic-type glucose-tolerance curves in obese patients, suggest that this occurrence depends on the excessive accumulation of fat in the livers of obese patients, with resultant impairment of hepatic capacity to store glycogen. No pathologic evidence in support of these claims was offered, however, and it is known that fatty infiltration of the liver does not preclude glycogen storage³⁰ and that it not infrequently occurs in Von Gierke's disease.⁴⁰ In these authors' cases of ascending infectious hepatitis,¹² as well as those of Coller,^{13, 14} in which diabetic-type glucose-tolerance curves were observed, the extent of the liver damage was not completely evaluated, the pathological data reported were not markedly abnormal, and the glycogen studies done on tissue removed at the time of operation were entirely within normal limits. All these studies were made by using the oral administration test method.

Soskin¹⁶ has shown that a diabetic type glucose-

tolerance curve can be obtained in completely hepatectomized dogs. It is obvious that a similar situation is never encountered in man, and the data presented here indicate that the extent of liver damage compatible with life is not sufficient in human beings to cause a marked alteration of the glucose-tolerance curve after intravenous injection of glucose. Indeed, the regulation of the blood sugar, as measured by such a test in the cases reported here, seems to be by far the best preserved of all liver functions.

In the 6 diabetic patients whom Soskin et al¹⁶ reported as showing increased metabolic disturbances with the development of liver disease, the initial function studies performed failed to demonstrate much evidence of liver damage, and repetition of the tests after therapy was not frequent enough to evaluate accurately any changes that may have occurred. No studies to determine liver function were reported in any of the patients who showed aggravation of their diabetic condition following therapy for liver disease, nor was any explanation offered for their relapses.

In Soskin's¹⁶ preliminary report on the intravenous glucose-tolerance test in patients with liver disease, his findings in such cases were interpreted as showing definitely abnormal curves with a characteristic contour, and the possible use of the test as a diagnostic aid in cases of early or mild liver disease was thus suggested. Until the detailed data from which Soskin's results were obtained are available for statistical analysis, however, no accurate conclusions can be drawn.

The advantages of the intravenous as compared with the oral glucose-tolerance test are manifold.⁴¹ In addition to obviating any anorexia or nausea that may prevent proper ingestion of the test sugar, an intravenous test automatically removes such important variables as gastric motility and intestinal absorption in a test of glucose tolerance in any subject. The significance of the latter factor is well demonstrated in comparing the oral with the intravenous curves in a case of steatorrhea.³⁷ It seems particularly necessary to consider these advantages in studying cases of liver disease in which stasis in the portal circulation and delayed absorption from the gastrointestinal tract may conceivably cause the protracted periods of hyperglycemia following oral administration of glucose that have been reported in the literature.

SUMMARY AND CONCLUSIONS

An intravenous glucose-tolerance test was performed on 25 patients with liver disease, each of whom showed by clinical and laboratory examinations evidence of severe to moderate liver damage at the time the test was performed.

Although extreme variations appeared in individual tests, by far the greater proportion of the values obtained were within normal range.

ally selected as to its length, so that when the curve of the clavicle was taken into account the nail would be sufficiently long to engage the inner fragment. This nail, made of stainless steel, was placed in the drill hole and driven through the

By May 17, the wound was well healed. Roentgenograms taken at that time showed satisfactory alignment of the fragments and evidence of union (Fig. 3). On June 14, the nail was easily removed through a 2-cm incision under local

TREATMENT OF FRACTURE OF THE CLAVICLE BY INTERNAL NAIL FIXATION*

REPORT OF A CASE

HAROLD G LEE, M.D.†

BOSTON

FRACTURES of the clavicle can almost invariably be satisfactorily treated by conservative measures. The fragments unite easily and quickly, and the functional results are good, even though there may be a certain amount of residual deformity and shortening of the clavicle. In an occasional case of fracture of the outer end of the bone in which it is desirable to obtain perfect alignment and retention

operative technic with intramedullary nail fixation was successfully accomplished. It is understood that surgery of this type is not without its dangers and should be undertaken only by a qualified surgeon.

The problem presented by the fracture that lies in the outer half of the clavicle is similar to that of an acromioclavicular dislocation. The shoulder with the distal fragment is tilted downward, and the proximal fragment rides upward. In certain cases it is difficult to approximate the fragments and hold them in position. If the anatomic alignment is not maintained, the distal fragment tends to slip back and forth, carrying the periosteum down under the clavicle. Herein lies a potential danger in that a bony spur may develop under the clavicle (Fig 1).

CASE REPORT

A V, a 23-year-old man, was admitted to the hospital on April 29, 1943, complaining that the left shoulder had "let go" when struck by a baseball. The roentgenographic examination showed a complete fracture in the outer half of

FIGURE 1 Roentgenogram Showing a Bony Spur That Developed under the Clavicle following Failure to Maintain Alignment of the Fragments after Reduction

of the fragments, the usual closed methods of treatment are inadequate. In such fractures, intramedullary fixation of the fragments by Kirschner wire has been carried out with success, but its use is not without danger, as is attested by several fatalities that have resulted from penetration of nearby arteries. In the case here presented, an

the clavicle, with the distal fragment tilted downward (Fig 2). Repeated attempts at closed reduction and retention of the fragments failed.

Operative intervention was carried out as follows. Under general anesthesia, a posterior incision running longitudinally to the axis of the bone and above its curve was made at the outer end of the clavicle. The fragments were exposed and their ends cleaned. The fragments were approximated, and bone forceps were applied to hold them in position while a nail was being introduced.

A drill hole was made in the outer end of the clavicle after the point of entrance for the drill had been calculated by studying the position of the fracture. The nail was care-

SYMPOSIUM ON MEDICAL SOCIOLOGY

THE POINT OF VIEW OF ORGANIZED MEDICINE TOWARD THE DISTRIBUTION OF MEDICAL CARE*

LOUIS H. BAUER, M.D.†

THE problem to be discussed is that of medical care. It is a controversial issue, in fact, if it were not so there would be no problem. I should like to appeal for a sound and sane method of approaching it. It is a problem that is comparatively recent, having developed within the last two decades. It has been brought about by the increased costs of medical care.

One of the reasons for this situation has been the increased cost of medical education, but the chief one has been the increased cost in diagnosis. After all, the physician giving the medical care receives little more money than he did a good many years ago, but the cost of arriving at the diagnosis is tremendously greater, and the result has been that there are certain persons who find it difficult to meet the economic burden of illness, particularly prolonged or so-called "catastrophic" illness. More persons go to hospitals and more have private nurses, and both these trends increase the cost of medical care.

There has been a great deal of propaganda concerning the distribution of medical care in the United States, and not all of it is well justified. For example, a so-called "National Health Survey" was conducted in 1939, as the result of which it was stated that one third of the people of the United States were without medical care. This statement is certainly not true today, and I do not believe that it ever was true. The figures were based on a survey of what was not a true cross-section of the country but a cross-section of a certain area, held in an effort to unearth chronic sickness. No effort was made to find out *why* people did not receive medical care. The survey was carried on by 6000 W.P.A. workers of high-school age who had no training whatever in what they were to do or in how to do it. I daresay that at least a third of those present did not have medical care in 1944. I did not have any myself, but it certainly was not because I could not get it. It must be remembered that many persons are not ill. Others prefer to secure medical care through patent medicines bought in drugstores. Others go to cultists, osteopaths or chiropractors, and still others, such as Christian Scientists, have religious scruples against accepting medical care. All these things must be taken into consideration.

Even the survey mentioned revealed that 17 per cent of persons with incomes of over \$3000 did not have medical care. Certainly, the economic factor was not the important one there.

Shortly after the results of this survey were published, the Medical Society of the State of New Jersey, by means of the radio, the press and public speakers, stated that anyone in that state who could not get medical care should immediately apply to the medical society and promised that care would be given them. Of a population of over 2,000,000, only 7 persons reported that they could not get medical care, and none of them were actually unable to do so. They simply did not know how to go about it.

The statement frequently made is that half the counties in the United States are without a general hospital. This is true, but it is not stated that of these thirteen hundred counties only thirteen are more than thirty miles from a general hospital. With good roads thirty miles is not a great distance to transport a patient. In fact, it is often easier to transport a patient twenty or thirty miles in a rural district than it is to take him five or ten miles to a city with its traffic problem. Nor is it stated that of these thirteen counties only 5 have a population of more than 5 persons per square mile.

The United States has the lowest death rate of any country in the world except New Zealand, and New Zealand can hardly be compared with the United States concerning either the character of its population or its medical problems. The rate of the United States has constantly decreased, and even during World War II, with the shortage of physicians and nurses, death rates remained surprisingly low, and those in many areas even decreased. The life expectancy has increased forty years in as many years. Infant mortality has dropped 50 per cent since 1920.

Draft statistics are often cited as showing that the American public is gradually falling apart physically. The facts are that approximately 4,000,000 men were rejected in the draft, and that of these, 800,000 were illiterate. Nearly 800,000 more were rejected because of neuropsychiatric defects. It is questionable how much medical care or lack of it had to do with the development of these conditions. Nearly 1,000,000 men were rejected on account of bad teeth, but most of them were later accepted. Between 200,000 and 400,000 men had remediable defects. A great many of these men could

*This is the seventh of a series of nine lectures on medical sociology given weekly at Harvard Medical School during January, February and March 1945. They were sponsored by the Department of Preventive Medicine and were primarily intended for third-year students. These articles will temporarily replace the reports "Medical Progress."

†Member, Board of Trustees, American Medical Association.

tive fixations. In all except one, the patient recovered good function and the fragments were perfectly aligned. Osteosynthesis by a nail was also proposed by Spitzzy,² Bonnet³ and Johnson.⁴

It has been customary to consider some form of postoperative external splinting as necessary for adequate fixation, regardless of the type of osteosynthesis, but in following the nail fixation in the

removed as soon as the roentgenogram shows solid union.

SUMMARY

A case is presented of a fracture in the outer half of the clavicle in which operative intervention and fixation by means of a nail were satisfactorily carried out. No postoperative dressing or splint was re-

FIGURE 4. Roentgenogram, Taken Six and a Half Weeks after Operative Fixation, Showing Solid Union.

present case, no external retentive dressing, not even a sling, was required.

One objection to nail fixation of fractures of the clavicle is based on the possibility of ulceration of the skin from the head of the nail. In the method herein described, the head lies in the posterior aspect of the clavicle, so that the skin is not pulled over it. Another objection is the danger of irritation of the bone, giving rise in some cases to osteitis and in others to hypertrophied callus. This danger is not encountered with this technic, because the nail is

removed. The method afforded complete comfort to the patient and permitted him to be ambulant, thereby definitely curtailing the period of incapacity.

prevent the rendering of a mere quantity of medical care rather than care of a high quality. In the development of any new type of insurance, it takes time to make it successful and acceptable. At present all sorts of voluntary insurance plans are under experimentation. Some of the industrial plans date back twenty years, but many of them are of extremely recent origin. Many such plans that were started by medical societies have altered their method of coverage. Some of them have failed simply because they were not on a sound actuarial basis and were not organized to deliver good medical care.

When the problem of insurance first came up, no one knew just what should be done. There was no actuarial background for any of these plans. No one knew how the public would react to the proposition or how physicians would react to it. Consequently, there was blind groping, but during the last four or five years a good deal of experience has accumulated showing some things that are good and some that are not.

The American Medical Association has been severely condemned for not proposing a voluntary plan to cover the whole United States. To my mind, this would have been the surest way of killing the whole thing, for the very reasons just stated. No one was in a position to say what the best type of plan would be, and even now we are not entirely sure. It is my opinion that there never will be a single plan that is satisfactory for the whole United States, because a plan that will work in Missouri and Arkansas may not work in Massachusetts, what will work in the city will not work in the country, and what will work in agriculture will not necessarily work in industry. So that a variety of plans are needed, and I think that this will be the answer so far as insurance is concerned.

There are persons who say that the voluntary plans will not work. Such statements are made in haste and perhaps maliciously — those who make them do not want voluntary plans to succeed because they prefer compulsory ones. Nevertheless, group hospital insurance, which is one form of voluntary insurance, has grown tremendously in the last few years. There are now over 19,000,000 persons in the United States who are covered by it. This is admittedly not enough, but in view of the increasing demand for this type of insurance, there is no reason why it should not be made available on a country-wide basis, and it probably will be. There are over 25,000,000 other persons who are covered, at least to some degree, by voluntary nonprofit medical-society plans, industrial plans and commercial plans. These plans vary from complete medical coverage to coverage only for surgery and obstetrics, and from coverage for the whole family to that for workmen only.

These plans must be made available to everyone who desires to be insured, and at a cost within his

means to pay. Over half the states in the Union now have nonprofit plans, either in operation or in the throes of organization. Growth has been slow and will continue to be so, but it has been much more rapid in the last two or three years than anyone thought possible at the beginning. The public is not yet sold on the idea. There have been all sorts of surveys. They disagree on some points, but they all agree that the public is demanding some method of prepaying its costs for catastrophic illnesses, and the majority of the surveys state that the public prefers to do this on a voluntary basis if it can be so arranged. The American Medical Association is about to appoint a director of insurance to correlate these types of plans and to stimulate their growth. The only reason it has not been done already is that the proper man for the job has not been found, but he soon will be.

It has been suggested that the indigent could be covered by having the state or county or town concerned purchase voluntary policies instead of hiring a so-called "poor" physician or paying the physicians' bills directly.

The Committee on Public Relations and Economics of the Medical Society of the State of New York states that 2 to 10 cents a day per person will adequately cover both medical indemnity and hospital insurance, that a broad surgical contract costs 2 cents a day per person, that a surgical contract including obstetric care costs \$1.70 a month per family, and that a liberal medical and surgical contract with obstetric care costs \$3.00 a month for an entire family. Such plans are available in certain areas, but they have not yet been made widely enough available, and we are trying to see that they are.

I have said that there are some persons who contend that voluntary insurance will not work, but it has not been tried long enough for them to make any such statement. One of the reasons given is that such insurance did not work in Europe. This is an unfair comparison, because in this country no voluntary plan that is worth anything has the slightest relation to any of the so-called "lodge practices" or "friendly societies" in Europe prior to the adoption of the compulsory program.

As already stated, insurance is only one answer to the problem. Adequate diagnostic facilities must be available in every area. If the local communities are not able to support diagnostic centers, they must get subsidies from the state. If neither the local community nor the state can finance them, the federal government must do so. If diagnostic facilities are available at reasonable cost, and there is voluntary insurance as well, the problem of the cost of medical care will be largely solved.

It has been publicly stated that the American Medical Association is against this program, as it was against those proposed in 1928, 1932 and 1934, but there is scarcely anyone whose opinion has not

have been cured and entered the service, but they refused to do anything in that direction.

A great many men were rejected on account of defective eyesight. Here again, it is doubtful whether any amount of medical care would develop good eyesight. Many of these men might not have had such poor eyesight if they had been instructed in the proper care of their eyes in their early days, and the same thing applies to those rejected for poor teeth. Proper knowledge of dental hygiene might have saved a great many of them but the figures would probably not have been materially affected by an increase in medical care.

During the 1939 survey, a prominent weekly magazine published a cartoon showing a hut on the side of a hill, — it was nothing more or less than a few boards nailed together, — with an emaciated woman in rags, accompanied by two or three children, all practically naked. The cartoon was entitled, "These people need medical care." They did need medical care, but they needed some other things a great deal more. They needed a proper place to live and proper food and clothes. Had they had these, they would not have needed so much medical care.

I do not wish to give the impression that I think that all is well with the status of the medical care in the United States, because I do not. It needs a great deal of improvement. Owing to increased costs there are persons who cannot afford good medical care, and there are others who stay away from physicians rather than accept charity. This situation must be remedied.

The difference in opinion that exists relates to the manner in which the situation should be remedied. First of all, it must be borne in mind that there are certain areas in the United States in which good medical care simply is not available, because the area is such that it cannot support a physician or a hospital. If a physician takes up practice there, he either soon goes somewhere else because he cannot practice good medicine, or — what is even worse — stays there and practices poor medicine.

It is thus evident that the lack of proper diagnostic facilities in certain areas of the country must be remedied. There is probably no one in Massachusetts who is unable to get medical care, and this is certainly so in New York State, but not all states are so well favored.

There is also a serious lack of facilities for preventive medicine in the United States. About half the counties have no county health department. It is not necessary for every county to have such a department, but every district should have one. In sparsely settled areas, two or three counties may combine to have a district health center.

There are four economic groups in the United States. The first comprises those who are financially well enough off to meet any conceivable situation. The second includes those who can meet the ordinary

costs of living and ordinary medical expenses, but find it difficult to meet those of long and expensive illness. In the third group are those who can meet the costs of the bare necessities of life but cannot meet the costs of any sickness. The fourth group comprises those who are dependent on public aid for housing, clothing and nutrition as well as for medical care.

The first and last groups require little consideration. Those in the first group can afford any type of medical care that they desire. Those in the last group in most areas are likewise well taken care of through charity hospitals and welfare departments. There are certain areas in the country in which this is not true, and that situation must of course be remedied. The other two groups are the ones that cause the most concern, being comprised primarily of those in the middle income bracket. What is the best way to meet this need? The American Medical Association believes that medical care of a high quality should be available for every person in the United States. The difference of opinion relates to how this medical care should be distributed.

Those of you who are on the faculty will recall that many changes have occurred in the therapeutics of certain diseases. They remember, as I do, the time when there was no treatment of pneumonia except bed rest and fresh air. I remember a remark made by Dr. Frederick Shattuck, our professor of medicine, to the effect that if he had pneumonia he would want to be in bed in a room with the windows open and a fire in the fireplace and to have someone feed him plenty of liquor. Thus, he said, was about the best treatment there was for pneumonia. Then serum was developed. It was not adopted immediately, and even after considerable experimentation it was used only gingerly. In fact, for a long time there was serum only for certain types of pneumonia. Somewhat later, the sulfonamide drugs came on the market, but physicians did not abandon the use of serum. Both were employed, and only recently has serum gone more or less into the discard. Next came penicillin, but the sulfonamides have not been given up because of it. A new system of therapeutics in the treatment of pneumonia has gradually evolved over a prolonged period. Perhaps ten years from now all these methods will be in the discard and there will be something else.

The same approach should be made to the problem of distribution of medical care. Since our nation has been made the healthiest in the world through private enterprise, why should this be abandoned for something different? Let us experiment gradually, testing various plans that have been suggested.

The medical profession has accepted the principle of insurance as one of great assistance, but it continues to believe that such insurance should be on a voluntary basis to avoid political interference and

ise reach the unemployed class, so that it still does not solve the problem of the indigent. Finally, it is inordinately expensive, and results in a tremendous bureaucracy, with the accompanying red tape and inefficiency. Voluntary insurance, on the other hand, gives either a cash indemnity or medical service that the patient can use when and where he wants it. The physician is responsible to him and not to a bureaucrat.

The most outstanding example of compulsory sickness insurance that has yet been suggested in this country is that proposed by the Wagner-Murray-Dingell Bill, which died in the last Congress but has been reintroduced by Congressman Dingell.* It has not been reintroduced in the Senate. This is an extension of the Social Security program, which is in vogue in this country at the present time. Certain Social Security provisions of this bill have already become law, such as old-age security and unemployment insurance. There are some persons who are against this trend and think that we have gone too far, but this is an idle argument. Social security is here whether we like it or not. It is going to stay and we might as well accept the principle of it. The Wagner-Murray-Dingell Bill, however, goes farther and attempts to put compulsory sickness insurance into effect throughout the country. In substance, this bill would extend social security coverage to at least 110,000,000 persons in the United States. It would deduct 6 per cent from the employee's pay up to \$3000, and the employer would contribute an equal amount — a total payroll tax of 12 per cent. Self-employed persons would pay 7 per cent up to \$3000. In times of full employment this tax would bring in something over \$12,000,000,000 a year.

Not all this, of course, is for medical care. It is estimated that 25 per cent of the total income would be earmarked for medical care, or something over \$3,000,000,000 a year.

Senator Murray has stated that there will be no politics in the handling of this money. I hope that he is right, but I am extremely skeptical about it. It would certainly shatter most precedents. This does not mean that because there are public funds there must be politics. Locally, this is less likely to occur, since the people are much closer to those who are administering the program and stand guard over it. When, however, federal funds are controlled by the federal government for a project that may be three thousand miles away, politics is bound to come in, because there are many middlemen, and a tremendous bureaucracy is built up. In Germany, before the war, there were more people working in the Health Bureau than there were physicians working for it.

This bill places full authority for administration

in the hands of the Surgeon General of the United States Public Health Service, under the Social Security Board. It provides for an advisory council of sixteen who will be appointed by the Surgeon General from lists of nominees submitted by the various professional and other organizations. Presumably there would be physicians on this panel but there is not a single word in the bill to the effect that there *must* be a physician on the council. As a matter of fact, this makes little difference, because the council will have no authority. All it can do is to give advice, which may or may not be taken.

The bill provides for so-called "free choice" of physician, but this means free choice provided that the physician agrees to take part in it. In England, the majority of the better physicians refuse to play any part in the compulsory sickness-insurance scheme.

The bill also prescribes how and under what conditions the physician may participate. It provides for three possible methods of payment — a fee for service, a full-time or part-time salary or payment on a per capita basis.

The Surgeon General may limit the number of patients a physician may treat and under certain conditions he may arbitrarily assign patients to a particular physician. He sets up the standards for specialists and determines who meet them, and the patient has no choice whatever in the selection of a specialist. He is authorized to determine what hospitals can take part in the program, and within the limits prescribed in the bill can determine what those hospitals will be paid. It is my opinion that limitation of payment to the amounts set forth in the bill would result in the closing of most of the voluntary and private hospitals in the country or their conversion to government control.

There is provision for certain laboratory and hospital benefits, the nature and extent of which are to be determined by the Surgeon General. The bill also provides for grants-in-aid for medical education and research, with the result that the Government will eventually control both.

American medicine has been responsible for a state of health of the people unexcelled in any other country. The enactment of this bill would result in its deterioration, for if medical education suffers, if the quality of medical care becomes attenuated and if the incentive to individual medical research is removed, the resulting harmful effect on the health of the people is inescapable. Another tremendous bureaucracy will grow up.

Another point, which has been brought out by the American Bar Association is that neither the patient nor the physician will have any recourse from regulations or decisions issued by the Surgeon General, who is not an elective but an appointive official, except to a board appointed by the authority who wrote the regulations and made the decisions. One cannot appeal even to the courts.

*These paragraphs apply to the previous version of the Wagner-Murray-Dingell Bill. The present bill (S 1606) makes no mention of taxes and does provide for court action. The principles of the two bills are the same.

changed in the course of years on various problems of the day. Even as late as the summer of 1941, a large part of the population of the United States were against this country's entering the war, but it would be hard to find any red-blooded citizens who are not wholeheartedly for war now. Ideas have changed. The whole question of medical insurance was hazy twenty-five years ago. There was not the need for it then that there is now. Naturally, the American Medical Association did not sponsor any such program when the need for it was not shown.

Another piece of propaganda that is often leveled at the American Medical Association is that it is against group practice. There is a prominent doctor in Boston, a president of the American Medical Association only two or three years ago, who is head of one of the outstanding groups in the United States. Both the Mayo brothers served as president of the Association. There is a member of the Mayo Clinic who is a member of the Board of Trustees of the Association, and other examples could be cited. The American Medical Association is, however, against groups that are organized purely for profit and not to deliver a good grade of medical care, but groups as such have not been frowned on. Many such groups started after the last war, but they failed, not because of any disapproval of organized medicine but because the public could not support them. The public likes Dr. Smith but it does not like Dr. Brown, and patients will go to Dr. A but not to Dr. B.

Another point that should again be stressed is that of adequate health supervision in the way of preventive medicine for every district in the United States. There again, federal funds may be used to help subsidize the local communities that are unable to support such facilities.

For the last seventy years the American Medical Association has asked for a United States Department of Health, with a cabinet officer in charge and with the same status as all the other cabinet departments in the government. This request has never been granted, and this may not be the time to push such a proposition, because the present trend is to carry on government outside the cabinet departments. For example, the Department of Labor is hardly more than a statistical bureau, the War Labor Board settling most of the problems that would normally be handled in that department. The Department of the Treasury is largely an accounting department. The Reconstruction Finance Corporation and all the various lending agencies are grouped outside the Treasury Department. Many agencies are grouped in the Federal Security Agency, again an agency outside the cabinet.

It might be better if there were a commission to supervise the question of health in the United States, but one thing is certain: it is ridiculous that one must deal with a dozen different departments to find all the agencies connected with health. For

example, the United States Public Health Service used to be in the Treasury Department but is now in the Federal Security Agency. The Child Welfare Department is in the Department of Labor. The Food and Drugs Administration used to be in the Department of Agriculture but is now in the Federal Security Agency. The Immigration Service is in the Department of Interior. The Veterans Administration is entirely independent.

One of the plans that have been suggested for solving the problem of medical care is compulsory health insurance. In the first place, this term is a misnomer. The method has nothing to do with health, it has to do with sickness. It is not insurance, it is a tax. It is in operation in a great many countries in the world, and nowhere has it given as satisfactory records as has the American system based on free enterprise.

Preventable diseases are on the increase, as evidenced in England where the diphtheria rate has gone up since the adoption of compulsory health insurance in 1911 and in Germany, where this rate has tremendously increased. In England, since the adoption of the compulsory sickness insurance act, a higher percentage of patients with far advanced tuberculosis have been admitted to sanatoriums than in the United States.

Compulsory insurance encourages malingering. Days lost by the working man increase instead of decrease. It interposes a third party — the government — between the physician and the patient, the former is responsible to this third party and not to the patient. A poor type of medical care is generated.

In England, a panel system is provided. It is not unusual for a physician to have 1000 or 1500 patients on his panel. He tries to do a little private practice on the side, and it is nothing for him to see thirty patients in the course of an hour. It is easy to see the difficulty of rendering good medical care if the procedure is to allot two minutes to each patient.

There is also a tendency toward mass medicine and this is true throughout the various prominent experiments in compulsory sickness insurance. This was true in Germany before the war, and in this country. During the Depression, the Federal Emergency Relief Administration issued certain edicts to the various states that accepted money from the federal government to carry on medical care, and the physician was told what he could and could not prescribe. He was also told the number of visits that he could make.

The physician is extremely likely to become a certificate writer rather than a family counselor. In fact, a prominent English physician said that under the panel system the physician merely wrote certificates that would satisfy the patient, keep the physician out of the hands of the Medical Council, and satisfy his tattered conscience.

Compulsory health insurance does not in any

CASE 32071

PRESENTATION OF CASE

A fifty-four-year-old foreman entered the hospital complaining of substernal pain on exertion.

The patient first consulted his physician four and half years before admission, complaining of anterior chest discomfort of five months' duration. One month before the onset of this symptom, he underwent a herniorrhaphy at another hospital. Physical examination revealed at that time a heart of normal size, but there was a blowing systolic murmur at the apex and a soft blowing diastolic murmur at the base and along the left sternal margin. X-ray films revealed no cardiac enlargement or evidence of aortitis. The electrocardiogram showed a PR interval of 0.3 second. The operation was carried out without difficulty, and convalescence was uneventful. About a month after the operation, he was awakened one night by a vague sensation of uncomfortable pressure across the anterior chest, which lasted half an hour. This sensation recurred about a week later, at which time he found that he was more comfortable sitting up than lying down. This episode also lasted about thirty minutes. A similar but less severe attack awakened him from sleep seven weeks before he saw his physician. He had had no other symptoms.

The past history revealed questionable rheumatic fever sixteen years previous to the onset of symptoms. His heart had been declared normal by an insurance company four years previously. He had had gonorrhea many years ago. He ate heavily and smoked moderately.

Physical examination by his physician revealed a slightly obese man in no distress. The eyes were normal. The maximal apical impulse was felt in the fifth interspace 10 cm to the left of the mid-sternal line. The heart sounds were distant. A moderately loud blowing diastolic murmur was heard in the aortic area and at the apex. There were no thrills. The abdomen was negative. There was no edema of the lower extremities.

The pulse was 78, regular and full. The blood pressure was 140 systolic, 60 diastolic.

A blood Hinton test was negative. A chest plate showed a transverse heart with slight enlargement of the left ventricle. An electrocardiogram revealed normal rhythm, with a rate of 85. The PR interval was 0.28 second, T_1 was inverted, T_2 diphasic, Q_1 slightly prominent, and T_4 inverted.

The patient was advised to lose weight and reduce his smoking. He followed instructions and one month later had lost 14 pounds. During that time he had had no more attacks of chest discomfort and complained only of a little dyspnea.

The patient was again seen by his physician seven months later. He had felt well until a few weeks previously. At that time, he again began to have episodes of substernal discomfort at night, quickly relieved by nitroglycerin. Physical examination was unchanged.

One year later the patient reported that he had been troubled nightly by precordial discomfort, which awakened him but was relieved by nitroglycerin. The pulse was regular at 84. The blood pressure was 135 systolic, 45 diastolic. The heart sounds were fair, with a moderately loud aortic diastolic murmur. There was a questionable diastolic gallop at the apex.

Fifteen months later, he still complained of nightly substernal oppression, which was relieved by nitroglycerin or by sitting up. The pulse was regular at 84. The blood pressure was 150 systolic, 45 diastolic. The heart sounds were of poor quality. Slight systolic and moderate diastolic murmurs were heard in the aortic area. Fluoroscopy revealed no change.

A year later, the patient reported that nightly substernal oppression persisted. The heart sounds were again of poor quality, with Grade II systolic and Grade III diastolic murmurs at the aortic area. Fluoroscopy revealed that the heart was considerably larger than previously. The aorta was rather wide and blunt. The lungs were clear. There was edema of the extremities. At the time of admission to the hospital, four months after last seeing his physician, the patient stated that the substernal oppression had become more frequent and severer, occurring during exertion and at rest. Dyspnea was marked. About a week before admission edema appeared in the ankles and then became generalized. He had been given digitalis and Mercupurin, with little improvement.

The patient was dyspneic. The pupils were equal and reacted to light and accommodation. The heart was markedly enlarged to the left. The sounds were distant. The pulmonic second sound was greater than the aortic. There were slight aortic systolic and diastolic murmurs. The pulse was irregular, with many premature beats. The blood pressure was 120 systolic, 50 diastolic. There were rales in both lung bases. The liver was palpable two finger-

I do not accept the premise that compulsory insurance is necessary, but there are those who say that it is needed for a certain segment of the population. Even if this is so, is that any reason for crowding it down the throats of everyone? Some persons are satisfied with the type of medical care that they have. A national compulsory sickness insurance program would overthrow everything that has produced the best medical education and the best medical care in the world and set up a system that has never been used in this country, and that has certainly never given any outstanding results anywhere else.

This problem can be solved by increasing the efforts on behalf of the voluntary plans, by making them widely available, by increasing diagnostic facilities and by having federal aid where this is necessary to subsidize the various districts.

As I have said before, when the answer is found it will not be a single but a multiple one. Compulsory sickness insurance is not the answer at all. The present system of medical care does need improvement, but this should be accomplished in an evolutionary manner, by increasing the number of facilities for preventive medicine and for diagnosis and making these available at a reasonable cost through hospital insurance, industrial plans, medical-society plans and what not, and by gradually evolving plans — three or four plans of different types — that will cover the whole United States.

In discussing the background of the necessity for reform, let us stick to facts and avoid propaganda. A member of the faculty of this school, in a public address, once stated his belief that organized medicine could not be trusted to handle this problem because, for example, the Medical Society of the State of New York had introduced an amendment to its bylaws that would prevent any individual or county society from initiating any policy that was in conflict with the state society's policies. He did not go on to say that when the amendment came up for consideration in the House of Delegates, it did not receive a single vote. Not even the man who had introduced it voted for it, and when I called that to his attention he said, "Well, the Council approved it." There, again, he displayed his ignorance, because the Council of the Medical Society of the State of New York cannot act on any amendment. If one is introduced, all it can do is to send it to the House of Delegates.

So let us try to make our arguments real arguments and not propaganda. Let us be willing to listen to the other man and sit down with him, and see if we cannot solve the problem in a way that is satisfactory to everyone, and that will not attenuate or deteriorate the present high standards of medical care or medical education, but if possible improve them.

Let us stick to the platform that good medical care should be available for every person in the United States. How many people are without it is not important, because if there is one person in the whole United States who does not receive it, that person is one too many. Let us find a system of distribution of medical care that is in accord with the system of free enterprise, which has made this country what it is.

* * *

In summary, the American Medical Association advocates the following: continued expansion of the practice of medicine, with full development of approved voluntary hospital, medical, indemnity, industrial and commercial insurance against the costs of medical care, the development of public-health and diagnostic facilities for preventive medicine throughout and of adequate diagnostic facilities everywhere, the use of the voluntary insurance principle in caring for the indigent and medically indigent, the development of hospital facilities where present facilities are used to the utmost and are still inadequate (there is now a bill in Congress that we hope will pass, — the Hill-Burton Bill, — which provides for building hospitals in areas lacking them and establishing diagnostic facilities, the bill is not perfect, but it is a step in the right direction), the use of federal funds to aid communities in public-health measures, care of the indigent and construction of necessary hospitals, when these communities are unable to finance the projects, but with retention of local administration, and the creation of a unified United States Department of Health, whether it be a cabinet or a commission.

Finally, let us move ahead, steadily but carefully, in a sound, evolutionary manner. We must not be stampeded into discarding and destroying what has given an unparalleled health record. Let us not forget that private enterprise has made America what it is.

copy without actual infarction in the usual sense of myocardial infarction on a basis of ordinary coronary-heart disease is another possibility. So as the symptom of coronary insufficiency — substernal discomfort — is concerned, there are several points of interest. One is that this symptom began over a year before his hospital admission, after the herniorrhaphy, was fairly acute, occurred when he was in bed at night and then subsided. That is more or less characteristic of a good many cases of coronary insufficiency, especially if the onset is sudden and is preceded by coronary thrombosis. Of course, most of you know that the old concept of coronary insufficiency as a relentless ever-increasing process no longer holds. Dr. White and others* have shown that many cases undergo considerable improvement in their clinical status coincident with the development of a collateral coronary circulation. When such patients develop so-called "status anginosus," as this man did, they then go on having the symptoms of coronary insufficiency for days or weeks or they die during the episode of acute coronary insufficiency. I do not recall seeing a case in which so pronounced a state of coronary insufficiency existed for so long. This patient reported nightly substernal discomfort for at least two and possibly three years.

When one is presented with a history of this kind the first thing that comes to mind is the possibility of some complication to explain the unusual history. It is conceivable, although not usual, that syphilitic aortitis might produce progressive occlusion of both coronary mouths. In ordinary coronary-artery disease, probably the most important factor in improvement is the development of collateral circulation following occlusion of one of the major branches. If this process were syphilitic, involvement of both arteries at their mouths, in fairly static circumstances, might preclude collateral circulation and yet be compatible with life. Another thing that may contribute to coronary insufficiency is aortic regurgitation, with low diastolic pressure. This sometimes accounts for coronary insufficiency in patients with rheumatic heart disease. Most of the coronary flow takes place during diastole. Therefore, if the diastolic pressure is low, the coronary circulation may suffer accordingly. It is conceivable that the low diastolic pressure here might have been responsible in part for the high state of insufficiency of the coronary circulation.

What are the conditions outside the heart that may be responsible for an increase in the symptoms of pre-existing angina pectoris? It is well known that peptic ulcer, although not necessarily giving rise to symptoms, may prolong coronary symptoms or cause them to be felt in other than usual circumstances. The middle of the night is a good time for

this to occur. Another frequent complication is gall-bladder disease, but there is nothing here to suggest it. The symptoms of hiatus hernia are frequently present at night when the patient is reclining. Such a finding is not mentioned in the x-ray report, but the patient was too sick toward the end to have further investigation. Could he have had pain of this kind as a result of an unusual aneurysm that did not show up in the x-ray films? I doubt it. That diagnosis can be eliminated because of the nature of the pain and especially because of its long duration.

What about dissecting aneurysm? Syphilitic aortitis, if present, is supposed to be a fairly good insurance against dissecting aneurysm, presumably because of its cohesive effect on the layers of the aorta. A number of cases of dissecting aneurysm have been reported, however, in the presence of syphilitic aortitis. It is a rare possibility and need not be considered here.

I shall vote for syphilitic aortitis, with aortic regurgitation, cardiac enlargement, occlusion of the mouths of the coronary arteries, congestive failure, coronary insufficiency and, finally, death with an Adams-Stokes seizure. The question of myocardial infarction of the usual sort must be raised in addition.

CLINICAL DIAGNOSIS

Coronary heart disease

DR. WILLIAMS'S DIAGNOSES

Syphilitic aortitis

Aortic regurgitation

Cardiac enlargement

Congestive failure

Occlusion of mouths of coronary arteries, with localized muscle atrophy and fibrosis

Coronary insufficiency (angina pectoris)

(Adams-Stokes syndrome)

Atherosclerosis of coronary arteries, with old myocardial infarction?

ANATOMICAL DIAGNOSES

Syphilitic valvulitis of aortic valve with insufficiency

Coronary sclerosis with thrombosis

Chronic passive congestion

Pleural effusion, bilateral

PATHOLOGICAL DISCUSSION

DR. MALLORY. This patient showed a grossly hypertrophied heart, weighing 750 gm. There was a bilateral pleural effusion, which, I believe, can be attributed to passive congestion. The heart showed an abnormality of the aortic valve, characterized particularly by separation of the commissures. The cusps were thickened and shortened, and their points of attachment to the aortic ring were considerably below where they should be. There was

*White, P. D., Bland, E. F., and Miskall, E. W. Prognosis of angina pectoris: long time follow-up of 497 cases including note on 75 additional cases of angina pectoris decubitus. *J. A. M. A.* 123: 801-804, 1943.

breadths below the right costal margin but was not tender. The ankles showed slight pitting edema.

The white-cell count was 13,000. The hemoglobin was 14.5 gm. The nonprotein nitrogen was 34 mg. per 100 cc. The spinal fluid was negative. An x-ray film of the chest showed considerable enlargement of the heart, particularly in the region of the left ventricle. There was some flattening of the apex, and the pulsations were somewhat diminished in this area. The aorta was tortuous but not definitely dilated. There was no calcification of the ascending portion. There was considerable enlargement of the pulmonary vascular shadow, with a tendency to a ground-glass appearance in the medial portions of the lung fields. There was a small amount of fluid in each pleural cavity.

An electrocardiogram showed a high-grade heart block, with frequent dropped beats. The PR interval varied from 0.35 to 0.44 second before the dropped beat. T_1 , T_2 and T_3 were inverted, R was upright in CF_2 , T was low in CF_4 , and T was inverted in CF_6 . A blood Hinton test was negative.

The day before death the patient began to have generalized convulsions associated with a slow pulse. Twenty-four hours after the onset of these convulsions he complained of severe substernal pain and had another convulsion. A few minutes later he expired, on the eleventh hospital day.

DIFFERENTIAL DIAGNOSIS

DR CONGER WILLIAMS: There is a discrepancy in the record in that an abnormal heart was found at the time of operation, whereas nothing was found in an insurance examination a few months later. I shall discard the insurance company's findings.

May we see the x-ray films?

DR MILFORD D. SCHULZ: Only the films taken at the time of his admission to the hospital are available. The striking thing is the enlargement of the hilar and pulmonary vessels, and the diffuse haziness centrally placed in the lung fields. There is no fluid in the pleural sinuses.

DR WILLIAMS: Is this picture sometimes seen on the basis of nephritis alone?

DR SCHULZ: I do not believe that it means that, it is caused by pulmonary edema from any source. You can see it in nephritis and also in cardiac disease.

DR WILLIAMS: Presumably this man died with an Adams-Stokes syndrome, at least the slow pulse and convulsions suggest it.

This middle-aged man presented many significant features in the clinical course of his disease. Aortic valvular disease, with predominant regurgitation, was present for at least seven years. He had cardiac enlargement, which progressed to congestive failure, probably due for the most part to aortic regurgitation. He also had symptoms suggesting coronary insufficiency, which despite great severity persisted for the unusually long period of eight or nine years.

So far as the aortic valve disease is concerned, it was either syphilitic or rheumatic, and other possibilities, such as hypertension and erosion of cusps from infection, can be discarded. If it was syphilitic, the whole picture can be explained on the basis of one disease, which is a popular thing to do at these exercises. The record states twice that the blood Hinton test was negative, and that the spinal fluid was also negative. No mention of the blood Wassermann reaction was made, however, which means that the serologic investigation was incomplete. The highly sensitive Hinton test occasionally shows a prezone that occurs infrequently with the less sensitive Wassermann reaction. I can recall three cases in which the Wassermann test was positive but in which the Hinton test was negative until done in dilutions.

DR TRACY B. MALLORY: That is most unusual, however. Nine times out of ten it works the other way.

DR WILLIAMS: So far as this case is concerned I am not willing to discard syphilis because of the negative Hinton tests. I should be more inclined to do so if blood Wassermann tests were known to be negative, but even that finding does not rule out syphilis.

If we assume that this man had syphilitic aortitis, the symptoms and findings of coronary insufficiency could be explained by the resultant narrowing of the orifices of the coronary arteries, although there is no reason why he should not have had coronary artery disease in addition. At least it would be reasonable to suspect the presence of a syphilitic lesion involving the coronary mouths. X-ray studies might be helpful in that connection. Fluoroscopy reported flattening and localized diminution of pulsations at the apex. One often sees that in myocardial infarction, which of course produces localized muscle weakening, and it does occur with a large area of muscle atrophy and fibrosis following gradual occlusion of the coronary arteries by a syphilitic process.

If he had had rheumatic valvular disease to explain the regurgitation, it is perfectly reasonable to assume that he also had coronary-artery disease. The two are not infrequently associated. It is less easy to explain the prolonged PR interval on the basis of rheumatic infection, because such prolongation usually means an active process. Occasionally, however, prolongation may be permanent after a single attack of rheumatic fever. I should not suppose that this man had had active rheumatic fever over a period of eight or nine years.

So far as the cardiac findings are concerned, the aortic regurgitation alone accounts for most of them. With syphilitic occlusion of the mouths of the coronary arteries, an area of muscle might be sufficiently fibrotic or atrophic to account for localized diminution of the ventricular pulsations by fluor

ds were normal except for enlargement of the fundi and spots, which remained unchanged. Visual acuity on the thirty-sixth day was 20/40 on the right, and 20/50 on the left (there were no reports of the fundi at that time). The craniotomies bulged, and the spinal-fluid pressure remained elevated (50 mm). A combined ventriculoencephalogram on the forty-eighth hospital day was not satisfactory; it seemed to be negative. The following day the patient was up and about and was discharged home. When seen in the Out Patient Department one week after discharge there had been no headache. Visual acuity was 20/30 on the right, and 20/40 on the left. There was papilledema bilaterally—right on the right and 3 to 4 diopters, with a fresh hemorrhage, on the left.

Fourth admission (eighteen days later). One and half hours before admission the patient had a convulsive seizure, which began in his right hand, progressed up the arm and then became generalized with loss of consciousness. The eyes were deviated to the right. The seizure lasted five minutes, and the patient felt well and appeared to be normal on admission. He was discharged on the following day, 0.1 gm of Dilantin three times a day and 0.1 gm of phenobarbital at night being prescribed.

Fifth admission (three months later). During his visits to the Out Patient Department, the choking of the left disk decreased but the headaches and frequent severe convulsions persisted. The patient was confused and mentally sluggish. The right optic disk was somewhat pale, but there was no definite papilledema on either side. The subtemporal decompressions were bulging. During his stay of three days in the hospital he had one convulsion. The Dilantin and phenobarbital were continued.

Final admission (two and a half months later). The patient took his medicine faithfully and remained well until two weeks before readmission, when he had another convulsion. Shortly after this seizure, he became stuporous and was taken to a hospital, where he was given injections "for convulsions." Four days before entry he became comatose, and two days later he began to have convulsions almost continuously. On admission he was comatose, breathing heavily. The decompressions were bulging and tense. The pupils were constricted and did not react to light. The eyes wandered continually. The tendon reflexes were hypoactive and equal, the plantar reflexes were normal.

The temperature was 104°F, the pulse 130, and the respirations 30. The blood pressure was 96 systolic, 50 diastolic.

Lumbar puncture yielded clear, colorless fluid under an initial pressure equivalent to 210 mm of water. The total protein was 28 mg per 100 cc.

A chest plate showed no abnormalities.

There were frequent convulsive movements which were severer on the right than on the left.

Sodium luminal (0.13 gm subcutaneously) was given at intervals of one or two hours for six doses and after that every three to four hours, the total dosage being 1.43 gm. At a second lumbar puncture, the pressure was 190 mm and the fluid was clear and colorless. The pulse, which remained rapid, diminished in strength and became irregular, respirations became gasping, the temperature rose to 108.5°, and the patient died thirty-two hours after admission.

DIFFERENTIAL DIAGNOSIS

DR WILLIAM H. SWEET: We are not told whether the first part of the seizure was observed, but I presume that the report indicates the full amount of useful clinical data ascertained.

"He often bit his tongue, usually on the right side." This comment is the first suggestion of a lateralizing character in the description of the seizures. If he bit his tongue more frequently on the right than on the left, presumably the muscles on the left side were more active than those on the right. These muscles would be innervated from the right cerebral hemisphere.

I should like to see the x-ray films, because they often have crucial diagnostic significance in a case of this kind.

DR CLAYTON H. HALE: These first plain films were reported as negative. I do not see anything abnormal. The ventriculogram shows that almost all the ventricles are filled and that they are not displaced. I cannot be sure, however, that both anterior horns are completely filled. The third ventricle is normal. The fourth shows no defects.

DR SWEET: How about this shadow? Is it the anterior horn that did not fill well for some reason?

DR HALE: I believe so.

DR SWEET: It is materially behind one of the others.

DR HALE: Yes, and the same is true in this film. This is one anterior horn, the other apparently stops at this point. At least there is overlapping of the two ventricles.

DR CHARLES S. KUBIE: Can you tell which it is?

DR HALE: I cannot be sure. This one looks smaller and should be the right one, because that was closer to the film. The posterior horns look all right. The bodies also look normal.

DR SWEET: The anterior horn stands out much better on the left side than on the right. That, of course, does not fit in with the one clearly described seizure that has the most localizing significance, namely, the one in which the patient was described as having a seizure that began in the right hand and extended up the arm.

In considering the lesions that produce increased intracranial pressure without producing any demonstrable deformity of the ventricular system we are faced with a number of possibilities about which we know little. As far back as the turn of the cen-

a separation of 3 to 4 mm between their points of attachment, whereas normal cusps should meet on the aortic wall within 1 mm of each other. So far as I know that is an absolutely pathognomonic sign of syphilitic infection. The aorta immediately above the valve was quite smooth and beyond the arch it showed only ordinary atheroma. There was nothing that I could recognize grossly as being typical of syphilitic aortitis. A section, however, taken just above the commissure, showed focal degeneration of the media of the aorta. Both muscle fibers and elastic tissues were completely destroyed. There was not, however, any inflammatory infiltration, and the vasa vasorum did not show perivascular cuffing, which is usually seen in active syphilitic aortitis.

I believe that the findings justify a flat-footed diagnosis of syphilitic infection but that it was a completely burned-out inactive lesion, which no doubt is the reason for the negative serologic tests. As Dr. Williams has pointed out, it is characteristic in syphilis of the aortic valve to find the mouths of the coronary arteries narrowed by the process. That was not true in this case. Further down in the coronary system, however, in the descending and circumflex branches of the left coronary artery, were old organized thrombi, one of which was slightly recanalized and had again thrombosed. The thrombosis had resulted from atheromatous lesions and had nothing to do with the syphilis, which produced the aortic regurgitation. The myocardium showed irregular patchy fibrosis on microscopical examination but no gross areas of infarction.

CASE 32072

PRESENTATION OF CASE

First admission A twenty-four-year-old man was admitted to the Emergency Ward shortly after he had had a convulsive seizure.

He stated that he had had a similar seizure several years previously. At the time of admission he was lucid and oriented. The anterior portion of the tongue was lacerated. The pupils were round and equal and reacted to light and accommodation, and the fundi were normal. Neurologic examination was negative.

The temperature was 98°F, the pulse 90, and the respirations 20. The blood pressure was 136 systolic, 84 diastolic.

While in the Emergency Ward, the patient had another convulsion, which lasted about a minute and in which he bit his tongue and was incontinent of urine. Following the convulsion he remained unconscious for about five minutes, after which his mind was again perfectly clear. An electro-encephalogram showed variable waves, with individual frequencies and voltages within normal limits. An

x-ray film of the skull was negative. He was discharged the following day, being advised to take 0.1 gm of Dilantin twice a day and 0.1 gm of phenobarbital three times a day.

Second admission (five months later) The patient was admitted in semicomatose after several convulsions. Following discharge he had been symptom free until three months later, when he had one seizure. Eleven days before readmission he had two more seizures, and two days before admission he began to have seizures almost continuously. On entry he could be aroused only with difficulty. The tongue was scarred and showed recent lacerations. Examination was otherwise negative.

The temperature was 98.6°F, the pulse 100, and the respirations 20. The blood pressure was 125 systolic, 80 diastolic.

The patient was given 0.13 gm of sodium luminal intramuscularly and had no convulsions during his stay in the Emergency Ward. He was discharged three days after admission, being advised to take 0.1 gm of Dilantin and 0.03 gm of phenobarbital four times a day.

Third admission (two weeks later) Soon after discharge the patient began to have constant, severe, throbbing headache in the frontal region and around the eyes. He vomited and was slightly drowsy and said that he had an occasional convulsive seizure. The convulsions usually started with movements of the eyes and then of the body and extremities. He would then fall down, usually on his right side, losing consciousness for one or two hours. He often bit his tongue, usually on the right side, and was incontinent.

Examination showed a papilledema measuring 2 diopters bilaterally and small hemorrhages at the edge of the left optic disk. There was slight peripheral constriction of the visual field of the left eye, and enlargement of the blind spots on both sides. The pupils were regular and equal and reacted to light and accommodation. The neck was slightly stiff. The reflexes were normal, and neurologic examination was negative.

An electroencephalogram showed a large amount of symmetrically distributed, low-voltage, slow activity, with no evidence of focal dysrhythmia. A ventriculogram showed the ventricles to be normal in size, shape and position. Lumbar puncture on the day following the ventriculogram revealed clear fluid under pressure equivalent to 650 mm of water. The total protein was 28 mg per 100 cc. Another ventriculogram, made through anterior burr holes, was negative.

The question of a so-called "pseudotumor cerebri" was raised, and subtemporal decompressions were performed, the one on the left being done on the fourteenth hospital day, and the one on the right on the twenty-seventh. On the nineteenth and thirty-sixth hospital days the peripheral visual

ds were normal except for enlargement of the fundi and spots, which remained unchanged. Visual acuity on the thirty-sixth day was 20/40 on the right, and 20/50 on the left (there were no reports of the fundi at that time). The craniotomies bulged, and the spinal-fluid pressure remained elevated (50 mm). A combined ventriculoencephalogram on the forty-eighth hospital day was not satisfactory; it seemed to be negative. The following day the patient was up and about and was discharged home. When seen in the Out Patient Department one week after discharge there had been no headache. Visual acuity was 20/30 on the right, and 20/40 on the left. There was papilledema bilaterally — 1+ on the right and 3 to 4 diopters, with a fresh hemorrhage, on the left.

Fourth admission (eighteen days later). One and half hours before admission the patient had a convulsive seizure, which began in his right hand, progressed up the arm and then became generalized, with loss of consciousness. The eyes were deviated to the right. The seizure lasted five minutes, and the patient felt well and appeared to be normal on admission. He was discharged on the following day, on 1 gm of Dilantin three times a day and 0.1 gm of phenobarbital at night being prescribed.

Fifth admission (three months later). During his visits to the Out Patient Department, the choking of the left disk decreased but the headaches and frequent severe convulsions persisted. The patient was confused and mentally sluggish. The right optic disk was somewhat pale, but there was no definite papilledema on either side. The subtemporal decompressions were bulging. During his stay of three days in the hospital he had one convulsion. The Dilantin and phenobarbital were continued.

Final admission (two and a half months later). The patient took his medicine faithfully and remained well until two weeks before readmission, when he had another convulsion. Shortly after this seizure, he became stuporous and was taken to a hospital, where he was given injections "for convulsions." Four days before entry he became comatose, and two days later he began to have convulsions almost continuously. On admission he was comatose, breathing heavily. The decompressions were bulging and tense. The pupils were constricted and did not react to light. The eyes wandered continually. The tendon reflexes were hypoactive and equal, the plantar reflexes were normal.

The temperature was 104°F, the pulse 130, and the respirations 30. The blood pressure was 96 systolic, 50 diastolic.

Lumbar puncture yielded clear, colorless fluid under an initial pressure equivalent to 210 mm of water. The total protein was 28 mg per 100 cc.

A chest plate showed no abnormalities.

There were frequent convulsive movements, which were severer on the right than on the left.

is obvious that, to retain our faith in some sort of desirable destiny for mankind, we must look on our disintegrated present to the inevitable interreaction when we will again right ourselves, realize the inescapable responsibilities of existence, face the barriers between ourselves and a newer, higher goal. There is nothing in our past experience to deny such a belief, there is everything to confirm it. We are again merely witnessing the devious ways by which man works toward each successive improvement.

SENSING OF OSTEOPATHIC PHYSICIANS IN MASSACHUSETTS

For the last thirty-seven years certain graduates of osteopathic schools have been permitted to practice osteopathy or medicine in Massachusetts. In view of recent changes in the statutes, it seems desirable to review the acts of the General Court that have governed such practice. In 1909 the Legislature enacted a law that contains the following statement, "The terms osteopathy and osteopathic, as used in this act or in relation to the registration and practice of osteopathic physi-

cians, shall have the same legal construction and meaning as the terms medicine and medical." Another section of this act states that persons registered under the act shall not be permitted to prescribe or administer drugs for internal use, or to perform major operations in surgery, or to engage in the practice of obstetrics, or to hold themselves out by virtue of such registration as and for other than osteopaths. The latter section applied to certain men who had been graduated from an osteopathic college, who had been practicing in Massachusetts for four years previous to the passage of

the act and who wished to be registered as osteopaths and limit their practice to osteopathy. Some doctors took advantage of this law and continued to practice nothing but osteopathy, but probably few of them remain.

From 1909 until the middle of 1944 graduates of any medical school, osteopathic or regular, were eligible to take the examination of the Massachusetts Board of Registration in Medicine, irrespective of the quality of the school from which they had graduated. But in 1936 the so-called "Approving Authority Law" was passed, which stated that students who matriculated at a medical school on or after January 1, 1939, must have graduated from a school approved by the Approving Authority. The effective date was subsequently changed to January 1, 1941. This act also specified

that, for the purposes of the Approving Authority, schools approved by the American Osteopathic Association and schools approved by the American Medical Association would receive the same consideration. It was because of the latter that the Approving Authority never did accept the list of the schools approved by the Council on Medical Education and Hospitals of

MASSACHUSETTS MEDICAL SOCIETY POSTWAR LOAN FUND

The Postwar Loan Fund has been set up, and all discharged medical officers who were members of the Massachusetts Medical Society in good standing at the time of their entry into the service may apply for loans from this fund. For further information apply to:

the American Medical Association

At the last session of the Legislature, apparently because they feared that the Approving Authority never would approve osteopathic schools, the osteopaths introduced legislation to set up an osteopathic board of registration, but the bill was withdrawn. Finally, at the suggestion of the Committee on Education of the Legislature, a compromise bill was drawn and finally passed. The bill states that the Approving Authority shall be increased from three to five members, one member being the osteopathic member of the Board of Registration in

ACTION AND REACTION

IT SEEMS to be a general law of nature that every action has its reaction, as the discharge of a gun is followed by the recoil. The seasons succeed one another, with winter as the inevitable reaction to summer, the rain and the sun each in turn exercise their influence in stimulating growth, seeming to oppose but actually complementing each other, the reed bows before the wind, then seeks its original position. So, in higher levels of activity, we appear to have compensating forces that can be depended on to oppose right actions and, eventually, to correct wrong ones. Only the wave lengths may vary; the reactions may be incredibly swift or, in the case

of massive forces, we may have to wait long for them to manifest themselves.

At the moment we are in the midst of a postwar reaction that shocks us like a hammer blow—a depression marking the release of those moral forces, as we considered them, that had been confined and directed toward a single, presumably noble and unselfish, purpose. We knew at the time that this reaction would set in, but still we were unprepared for it when the war went out from under us.

That which we had accepted and on which we had depended as unselfish devotion to a noble cause gave way to the return, sometimes manyfold, of selfishness and greed. The issues on which we had taken our stand became confused, the goals that we had seemed to reach became as unreal as the rainbow's end. Each one saw, not a better world for himself and others, but the need for hurrying back into the old warren before someone else could reach it.

We see this precipitate abandonment of the ideals that we had thought we had in hand in the wave of labor difficulties that has swept the country, we see it in the dissatisfaction of our less seasoned veterans who clamor only to get home, and in the disgraceful and subversive activities that have been reported to us of men and officers alike still in foreign countries. We see it in many little ways,—in the petty selfishnesses and discourtesies of the highway, in the increased demands made on our own harassed profession and in the abandonment of those restraints that commitment to a common cause had placed on us,—and we know that our tide of common effort has reached its flood and has begun to run the other way.

It has become popular, too, in our free press, which can roar defiance like a lion when needed to follow now in the footsteps of certain less regal animals. With a crying need for constructive effort in every direction, some of our editors seem more interested in digging up old bones to chew on and in indulging in what seems to us to be vicious anti-Russian propaganda. Our politics also, or our statesmanship, if you will, seems not now to be of the high order that our victories require to make the winning of them both justifiable and reasonably permanent. There is much with which we have a right to be discontented at the present time.

TRANSDIAPHRAGMATIC RESECTION OF THE VAGUS NERVES FOR PEPTIC ULCER*

FRANCIS D MOORE, M D,† WILLIAM P CHAPMAN, M D,‡ MILFORD D SCHULZ, M D,§
AND CHESTER M JONES, M D ¶

BOSTON

DURING the last fifty years, a variety of surgical maneuvers have been developed for the treatment of cases of peptic ulcer|| that may be broadly termed as intractable to therapy but are otherwise uncomplicated. According to Allen,¹ approximately 10 of every 100 patients suffering from peptic ulcer who present themselves to a physician do poorly under ordinary nonoperative methods of treatment. A sizable fraction of this group develop hemorrhage, perforation or cicatricial obstruction, obviously requiring surgical intervention. The remainder—estimated by Allen and Welch² as 10 per cent—stand as medical failures or as intermittently sick patients who, tied down to their diet and medication, still present symptomatic difficulties and an economic status far removed from that of a well man.

In these cases that prove refractory to medical treatment, surgery has in the past been directed at several objectives. One of these has been to increase the patency of the pylorus, another to produce some change in the relation between the acid gastric content and the alkaline duodenal or jejunal content, resulting in a neutralization effect of some type, and a third to ablate acid-forming cells, thus lessening gastric acidity.

That such physiologic objectives have not always been attained is easily demonstrated. Study of many patients after posterior gastroenterostomy reveals bile-free material in the stomach³ that is of high titratable acidity and low pH. Subtotal resection leaves in place much tissue containing parietal cells⁴ and is also compatible with high

postoperative acidity,⁵ although fundusctomy⁶ has represented an effort to circumvent this physiologic contradiction. Subtotal gastric resection may owe its success largely to removal of the antral mucous membrane rather than to the ablation of parietal cells,⁶⁻⁸ and there is experimental evidence⁹⁻¹¹ that the antrum occupies an important place, both in the normal secretory mechanism and in the so-called "ulcer mechanism." The occasional patient who remains chronically malnourished and develops peculiar postprandial symptoms following subtotal gastric resection brings to mind the possibility that this operation may be detrimental to the nourishment of some patients.¹²

The operative hazards of subtotal gastrectomy must be considered in evaluating this operation, and although they have been markedly reduced in recent years by doing the operation in stages^{7, 13} or by removing the antral mucosa in the presence of an inflamed duodenum,^{7, 8, 14} the operation still carries the inherent risks of an anastomotic gastrointestinal procedure. The postoperative incidence of stomal or jejunal ulcer following subtotal gastric resection is variously estimated at 2 to 8 per cent.^{15, 16}

It is a familiar observation that patients with peptic ulcer are worse during periods of so-called "stress"¹⁷⁻¹⁹. Such experiences accumulating over the years have led to the conclusion in the minds of clinicians everywhere that there is a close correlation between events in the cerebral cortex and functional activity in the stomach. The work of Cushing²⁰ with duodenal ulcer in certain types of brain lesions furnishes corollary information bearing on this problem, and also suggests that changes above the foramen magnum can produce ulceration in the upper gastrointestinal tract.

The manner of connection between the brain and the stomach has been known for many years. The vagus nerves were first studied in relation to gastric physiology by Pavlov,²¹ who showed in dogs that following section of both nerves gastric secretion in response to sham feeding and conditioned reflexes was lost. This bit of evidence alone

||In this paper the term "peptic ulcer" is used to apply to benign ulcers of the esophagus, stomach, duodenum or jejunum. It is employed as a generic term for this group of ailments and is not intended to imply that peptic acid is of special significance in their formation.

Medicine, who shall be a graduate of a school approved by the American Osteopathic Association and by the Approving Authority, and the other a layman

On December 14, 1945, the newly designated Approving Authority took favorable action on two schools approved by the American Osteopathic Association, namely, the Kirksville College of Osteopathy and Surgery, Kirksville, Missouri, and the Philadelphia College of Osteopathy and Surgery, Philadelphia. This approval followed hearings at which representatives of both schools presented all the facts concerning the qualifications demanded by the Approving Authority for medical schools. The Approving Authority had previously denied approval to the Des Moines Still College of Osteopathy, Des Moines, Iowa, which is a school approved by the American Osteopathic Association, an action indicating that the Approving Authority has not been giving blanket approval to all schools approved by the American Osteopathic Association.

As a result of these changes in the law controlling the practice of medicine in the Commonwealth and the actions of the Approving Authority, all applicants for examination for registration who matriculated on or after January 1, 1941, must be graduates of medical schools or osteopathic schools that have been judged worthy of approval. It also means that, in the future, the people of Massachusetts who need medical attention will be given it by either osteopathic or regular physicians who have received a proper education.

NOTICES

INTENSIVE COURSE IN OPHTHALMOLOGY

The Ophthalmological Study Council offers an intensive course covering various aspects of ophthalmology and extending from April 1 to June 1. This is primarily intended for discharged medical officers, but any physician who is properly qualified may participate. No laboratory or clinical work will be included, instruction being carried out by lectures, required reading and seminars. The course has been arranged by the executive officers of the Council, — Drs. Walter B. Lancaster, S. Judd Beach, T. L. Terry and Trygve Gundersen and Colonel Phillips Thygeson, — with the help of a large group of prominent ophthalmologists from all parts of the country, and it has the approval of the Surgeons General of the Army and of the United States Public Health Service.

Further details are given on the advertising pages of this issue of the *Journal*. Additional information may be obtained from the Ophthalmological Study Council, 520 Commonwealth Avenue, Boston 15.

BOSTON UNIVERSITY COURSE FOR DISCHARGED MEDICAL OFFICERS

Boston University School of Medicine will offer a months' course for medical officers who have been from the armed forces. This course has been designed to provide opportunity for these men to acquaint themselves with recent advances in medicine, to prepare themselves for practice or to spend a short period advantageously while waiting for a hospital appointment. Teaching by the case method will be conducted on the wards and in the outpatient departments of the hospitals affiliated with the medical school. In addition, regular teaching exercises will be held sometimes a week. Special conferences or seminars will be arranged as occasion arises.

Instruction in the following fields will be offered: internal medicine, general surgery, orthopedic surgery, obstetrics and gynecology, urology, otolaryngology and radiology. If there is a demand for instruction in the preclinical sciences, courses in these subjects may be arranged. The student is urged to spend the entire six months in one of the above fields, but arrangements can probably be made to permit a few students to divide their time between two or more of the fields listed above if they so desire.

The course will begin on March 15 and will extend to September 15. The tuition fee will be \$375.00. Application for admission should be made by writing to the Office of the Dean, Boston University School of Medicine, 80 East Concord Street, Boston 18.

BOSTON SOCIETY OF BIOLOGISTS

A meeting of the Boston Society of Biologists will be held in the Amphitheater of the Peter Bent Brigham Hospital, Boston, on Wednesday, February 20, at 8 p.m.

PROGRAM

The Comparative Pathologic Physiology of Addison's Disease and Cushing's Syndrome. Dr. Edwin Kepler.
Studies on the Stress Response of the Adrenal Cortex in Man. The diurnal rhythm. Dr. Gregory Pincus.
Studies on the Stress Response of the Adrenal Cortex in Man. Anoxia and shock therapy. Dr. Hugo Hoagland.

SOUTH END MEDICAL CLUB

The next regular meeting of the South End Medical Club will be held at the headquarters of the Boston Tubercular Association, 554 Columbus Avenue, Boston, on Tuesday, February 19, at twelve noon. Dr. Harlan F. Newton will speak on the subject "Surgery in Pulmonary Tuberculosis." Physicians are cordially invited to attend.

MASSACHUSETTS HOSPITAL ASSOCIATION

The Massachusetts Hospital Association will hold its annual meeting for the election of officers and such other business as may arise at the Hotel Statler on Monday, March 11, at twelve noon. This is to be a luncheon meeting.

NEW ENGLAND PATHOLOGICAL SOCIETY

The next meeting of the New England Pathological Society will be held on Thursday, February 21, at 8 p.m., in the amphitheater of the Peter Bent Brigham Hospital, Boston. The program is as follows:

Case Reports
Liposarcoma. Drs. Austin L. Vickery and Richard Cataldo.
Fibrosarcoma of the Heart Valve. Drs. Ephraim and Austin L. Vickery.
Homologous Serum Jaundice. A problem in the operation of a blood bank. Drs. I. Herbert Schein, Charles A. Janeway and Thomas D. Kinney, with assistance of Virginia S. Poole and Ianthé Taylor.
Skeletal Growth in Relation to Vitamin A Deficiency and Excess. Dr. S. B. Wolbach.

Short business meeting

(Notices continued on page viii)

the Mann-Williamson anastomoses. One group consisted of 3 otherwise normal dogs, another composed 3 dogs with the sympathetic nerves cut, and third consisted of 3 dogs with the parasympathetic supply to the stomach cut. The only animals that did not develop peptic ulcers were those in which the vagus nerves had been cut.

In 1922 Latarjet²¹ and in 1932 Pieri^{22,23} worked the vagus section in human beings, using the transdominal route. Their results are difficult to evaluate, but it is important to observe that, although some relief was secured, the effect was apparently extremely short-lasting.

In 1926, McCrea²⁴ published a review covering the nerve supply to the stomach and its significance and discussed part of the physiologic mechanism involved. He pointed out that vagal section in the chest produces marked motor effects on the stomach. Most of these effects have been corroborated by our work in human beings.

During the last five years, following the work of Churchill and Sweet,³⁵ a large number of trans-thoracic gastrectomies have been performed in many centers in this country, the aggregate total of which must run to several hundred. Observations on patients of this type in whom both vagus nerves were sectioned at variable distances above the diaphragm have shown that although disorders of pyloric emptying may develop, those of pancreatic or hepatic function or absorptive ability of the upper small bowel do not. This indicates that vagus section at this level is not deleterious to the upper digestive mechanism.

Another recent surgical development of significance is the work of Smithwick³⁶ dealing with surgery on the other component of the autonomic system. Several fundamental considerations that are applicable to the vagus nerves have emerged from his work. The first relates to what one might call thoroughness of operation. Smithwick has shown that a lasting result can best be obtained by radical extirpation of the autonomic system involved. This fact, among others, has led us to perform a vagus resection in which the nerve is resected from just below the lung root to well down on the stomach wall. Smithwick has also shown that the autonomic nervous system regenerates rapidly, particularly through tissue planes and ordinary ligatures. This has led us to believe that ideally the diaphragm should be cut and interposed between the cut ends of the nerves.

With these considerations in the background, work in this field was begun at the Massachusetts General Hospital early in 1944, and to date 15 patients have been operated on.

For some time prior to 1944, Dragstedt and his co-workers³⁷ had been working with a similar procedure and had already operated on several patients and published a preliminary account of their results. Since then, Dragstedt^{38,39} has published

more of his findings in patients on whom this operation had been carried out. His observations have been most helpful to others working in this field, and to him should go the credit for reviving this apparently obsolete operation.

In studying our patients we have directed attention toward the qualitative and quantitative aspects of the secretory changes, as well as to alterations in motility, as recorded by the balloon kymograph, to motility, as gauged by x-ray examinations and to changes in afferent conduction of painful stimuli from the upper gastrointestinal tract. These results will be briefly reported so that the findings may be compared with other work going on at the present time^{39,40} and so that a preliminary appraisal of the procedure may be provided.

CLINICAL DATA AND RESULTS

A summary of the first 12 cases that were operated on is shown in Table 1. Two patients were women and 10 were men. Four patients had duodenal ulcer without other complications. One had a co-existent esophageal ulcer and Raynaud's disease. Two patients had jejunal ulcers in old gastroenterostomies, and 1 of these had a concomitant duodenal ulcer. Two patients had stomal ulcers following gastric resection. Two patients had gall-bladder disease as well as duodenal ulcer. One had a submaxillary carcinoma, controlled by neck dissection and x-ray treatment, as well as a duodenal ulcer.

These 12 cases represent some of the most difficult therapeutic problems encountered in this field. They were selected because of the long duration and intractability of the symptoms as well as the past and present complications. All the patients had had one or more rigorous terms of hospital medical treatment in an attempt at relief. They were chosen in the hope that good or bad results would soon become apparent and with the idea that a maintained good result was significant and not due to chance factors.

In addition to these 12 patients, 1 patient was operated on at this hospital by another member of the staff as a desperate measure because of repeated massive sublethal gastric hemorrhages. He did not have a duodenal ulcer, nor had he been shown to have peptic ulceration at any time, and he does not fall into this group of cases. The patient succumbed approximately forty-eight hours following the operation, owing to difficulties that were apparently related to the anesthesia but that could also have resulted from hyperirritability of the autonomic nervous system, with the setting up of vagovagal reflexes and resultant cardiac standstill. The case is mentioned because it should be remembered that, as is true of any open chest procedure, this operation carries definite hazards, and following this event which took place early in our experience with this procedure we have routinely

suggests that the vagus nerves constitute one of the main pathways, if not the main one, between the cerebrum and the upper gastrointestinal tract. Other possible pathways include the sympathetic and somatic nerves and circulating humoral factors. The sympathetic side of the autonomic nervous system is doubtless significant in the physiology of the upper gastrointestinal tract, and it is probable that one of its more vital functions is the conduction of afferent impulses,²² many of which reach the conscious level and may be called viscerosensory fibers as well as regulatory fibers serving motor and secretory end organs.²³ Circulating factors involved in the secretory mechanisms of the stomach have been extensively investigated by many workers, chief among them Ivy²⁴ and his group at Northwestern University. The relation between the enteric hormones that they are studying and the antral hormones described by Edkins⁹ in 1906, which may be involved in the success of ordinary subtotal gastrectomy, is not clear. As a working hypothesis, however, one might suggest that impulses coming down the vagus nerves stimulate end-organ cells in the antrum whose secretion is both internal and external, the external secretion becoming a small fraction of the digestive mixture of the stomach and the internal secretion serving as a local perpetuating mechanism to complete the process of digestion after the initial psychologic stimuli of the sight of food and its chewing and swallowing have ended.¹⁰

These considerations in patients with peptic ulcer are profound and far-reaching in their significance. Most patients with peptic ulcer are likely to have pain when the stomach is empty. The pain is actually relieved by eating, despite the fact that this produces more acid secretion, as frequently demonstrated in the ordinary gastric analysis. When, however, a gastric analysis is carried out through a twenty-four-hour or forty-eight-hour period, it will be seen that the taking of food, although it may increase the total chloride content and the total amount of gastric secretion, is actually accompanied by a decrease in acidity.³ One may logically conclude from this that the secretory mechanism that operates on the fasting stomach is the one of the greatest importance in determining the therapy of patients with peptic ulcer. The evidence at hand suggests that neural factors are the important ones in the secretion and reaction of the fasting stomach, whereas the humoral factors play a leading role in the postprandial digestive process.

By this line of reasoning, one is brought to a possible approach to the vagus nerves in the treatment of peptic ulcer. There are many other considerations that form the background for this procedure, but those that have been mentioned above seem to be the most essential ones. Other less vital considerations are as follows. One of the drugs most effective in the treatment of early peptic

ulceration is atropine. This drug apparently acts by altering the permeability of the cell to acetylcholine and thus blocking parasympathetic impulses at the end organ. If the parasympathetic nerve supply to the stomach and duodenum were adequately interrupted, one might reasonably assume that a permanent and complete atropinization of the area had been secured and could conclude that such a procedure might help the patient with peptic ulcer.

Another element of some significance has to do with the concepts that are broadly grouped under the term "psychosomatic medicine." As Cobb²⁵ has so aptly put it, the use of the term "psychosomatic" predicates a false dichotomy and possibly should be avoided. The fact remains, however, that disturbances in the mental realm may at times be translated into organic disease through the mediation of either neural or humoral pathways. Peptic ulceration probably falls into this group of ailments, and it is possible that decentralization of the stomach through section of the nerve supply would prevent such environmental factors from affecting the organ.

SURGICAL BACKGROUND

After the work of Pavlov, interest in vagus effects on the stomach does not figure prominently in the literature, possibly owing to the rise and extensive use of posterior gastroenterostomy as an operative procedure and to the experimental work of Edkins.⁹ In 1924, however, Stahnke,²⁶ in experiments involving chronic electrical stimulation of the vagus nerves, produced typical peptic ulceration in 2 of 5 dogs, a result that, although numerically unimpressive, is of considerable qualitative significance as regards possible mechanisms relating to clinical peptic ulceration.

In 1929, Hartzell²⁷ using dogs, demonstrated in a convincing manner three fundamental points relative to the vagus nerves. The first is that section of both nerves decreases the acidity of the gastric contents. The second is that this section cannot be adequately done unless it is made through the chest. The third point is that if the section is technically incomplete, the effect is disappointing and transient. Restudy of these dogs three years after the initial operation showed a return of the acidity.²⁸ This finding, among others, has prompted us to carry out the most complete vagus resection possible in the lower chest and upper abdomen.

In 1931, Beaver and Mann²⁹ published a short paper that is of the greatest interest in this field. They were working with the Mann-Williamson preparation, which, in their experience, produced ulceration in dogs in approximately 95 to 98 per cent of cases.* In the article mentioned, they describe three sets of experiments on dogs prepared

*In the Mann-Williamson³⁰ preparation unneutralized gastric secretions are poured into the upper jejunum unprotected by the alkaline hepatic and pancreatic juices, which have been sidetracked into the lower bowel.

returning for studies. During these return visits, no recurrence has been observed, with one exception, consisting of a tiny duodenal fleck seen approximately eight months after operation, which again disappeared and was not accompanied by any return of symptoms. Following operation, as a general rule, the patients were allowed to eat and drink anything they wished, including alcohol and coffee, since it was believed that the operation would not be put to an adequate test if a patient was carried along on conscientious medical therapy.

One patient had symptoms over a six-month or eight-month period that were referable to increased gastric emptying time. These symptoms consisted of occasional belching and vomiting of food eaten many hours previously. The vomiting never became serious enough to alter the blood electrolyte con-

relieved postoperatively and have returned to work. A patient with stomal ulcer following subtotal gastric resection, in which remaining antral tissue was present, was only gradually relieved of his symptoms. He later had the antral remnant removed, with complete healing.

In summary, it may be said that in all 12 cases the ulcers have healed or are healing and that all but 1 patient had immediate and sustained symptomatic relief. There have been no surgical complications, such as empyema, persistent pneumothorax and cardiospasm.

X-Ray Changes

The x-ray changes following vagus resection may be described as consisting of prolongation of the initial emptying of barium into the duodenum.

FIGURE 1 Tracings of Serial Spot Films of Stomach and Duodenum in Case 1. These demonstrate the gastric emptying time by x-ray preoperatively and postoperatively. Some peristaltic activity was still visible postoperatively under the fluoroscope, but it had markedly decreased. There was residual barium in the stomach at fourteen hours.

centration, which remained normal throughout this period, but the patient lost several pounds in weight. This finally ceased, and the patient has since remained well.

Nine patients had duodenal or jejunal ulcers that produced pain as their outstanding symptom. In 2 of these cases, the pain was so severe that the patient was obliged to ingest some sort of antacid preparation frequently throughout the day and night. The clinical result in most of these patients has been quite striking in that they have had immediate and lasting relief of their symptoms. Whereas they were ready to submit to any type of medication or surgery to rid themselves of the symptoms, which plagued them constantly, they have been

and marked prolongation of the final emptying time of barium from the stomach. In normal patients, the initial time of barium-emptying into the duodenum is from half a minute to one and a half minutes after taking barium by mouth. This has not been altered by the presence of peptic ulcer unless the patient has frank obstruction. In the patients who have had vagus resection, initial emptying into the duodenum usually requires fifteen to twenty minutes.

The final emptying time of the normal stomach is approximately two to two and a half hours. Following vagus resection, this time may be twelve to twenty-four hours (Fig 1). It is remarkable that these changes have not produced more symp-

novocainized both vagus nerves above the point of manipulation and have given rather large doses of atropine either before or during the operation

The report of the clinical results in these 12 cases must be regarded as an interim one, because it will

cated duodenal ulcers no crater was visible by x-ray a week to ten days after the operation. In 2 cases, stomal ulcers following gastrojejunostomy required a longer time to heal but finally reached complete healing in three weeks. Follow-ups on

be many years before this operation can in any way reach final evaluation

As regards healing of the ulcer, in the uncompli-

all these patients have been carefully carried out, and most of the patients have been grateful for their treatment and have been co-operative in

in place, both of which are admittedly artificial stimuli

The permanence of these secretory changes cannot as yet be determined They have been main-

able to assume that there would be some change in reaction to neostigmine The studies so far have been disappointing, not for lack of postoperative findings but because the neostigmine secretory

FIGURE 3 Charges in the Reaction and Titratable Acidity in Case 5 Preoperatively and Postoperatively

There was an increase in pH eight days after operation, as compared with the preoperative values. The titratable free acidity disappeared postoperatively, and the total acid was much reduced. A preoperative insulin test gave a marked outpouring of acid gastric contents (the blood-sugar levels are shown in the upper figures). A postoperative insulin test (shown below base line) gave no response, although the blood-sugar levels were in the same range. There was no significant change in reaction to prostigmine. Calcium values showed a fall immediately following operation, with a rise toward normal in the subsequent four days.

tained in all the follow-up studies so far carried out. The typical secretory changes occurring preoperatively and postoperatively are shown in Figures 2 and 3. Similar data have been prepared for the

response in the unoperated stomach is so variable and so unreliable as to make this test a poor one.

The effects of insulin on gastric secretion have been mentioned by Weinstein et al⁴² as being a

FIGURE 4 Motor Activity in the Gastric Antrum in Case 9 Preoperatively. The large waves correspond to propulsive peristaltic activity and are normal arterial waves.

other cases and show essentially the same changes. The secretory response to drugs has been of secondary interest, since it was considered that the unchanged secretory picture was the most important factor. The reaction to neostigmine has been studied because this drug may act by blocking the interaction between acetylcholine and cholinesterase. If the chief source of acetylcholine in the stomach — the vagus endings — were abolished, it is reason-

test for vagus section. They state that unless this reaction is abolished, the vagus nerves cannot be regarded as having been adequately sectioned. In these patients, studied postoperatively, there has been no insulin response. The preoperative insulin response was usually quite definite.

The response to histamine is unchanged by this operation, which is as it should be. This response is probably a direct effect of the drug on the gastric

toms in our patients, and if this operation becomes generally applied, this phenomenon may be responsible for some poor clinical results. It is, however, of the greatest importance in selecting patients to avoid those who show complete obstruction due to scarring, both clinically and by x-ray examination. If they are so obstructed, either subtotal gastrectomy or posterior gastroenterostomy concomitant with vagus resection should be carried out.

Another interesting symptomatic result of this change in gastric emptying rate has to do with the completeness with which food is digested. Several

throughout the greater part of the twenty-four hour period. Some elevation may be observed an hour or two after the taking of food, but in general the patient goes through the day with no free acid. Second, there is a concomitant change in total acid, with reductions varying from 50 to 70 millimols per liter. Third, there is a change in total chloride content that roughly parallels this change in acidity but is not so marked. Fourth, there is a minimal change or no change in the total base concentration. Fifth, there is an increase of from 1 to 3 or more pH units at every hour during the day. We have

FIGURE 2 Chart Showing the Reaction and Titratable Acidity in Case 1 Preoperatively and Postoperatively

The postoperative tests were carried out approximately ten days after the operation. There was a rise in pH and a fall in titratable acidity following the operation, an alteration that has been maintained in follow-up studies.

of the patients have commented on the fact that, whereas preoperatively certain types of seed food, such as cucumbers and tomatoes, were poorly digested and often recognizable in the feces, postoperatively, regardless of what food is taken, complete digestion is secured and the stools do not contain undigested material.

Secretion

Effects on gastric secretion have been extensively studied and will be reported in detail in a separate paper. At the present time it seems sufficient to state that the immediate effects following vagus resection are as follows. First, there is a change in free acid values from normal or elevated to zero

seen no patients who following vagus resection showed a value below pH 1.5, whereas this is not infrequent in normal persons. In most patients with peptic ulceration the gastric acidity is in the region of pH 1.0, especially between midnight and 5 a.m. Lastly, the change in pepsin content has been inconstant and generally negligible.⁴¹

The standard procedure has been to leave the Levin tube in the stomach for eighteen to forty-eight hours, letting the patient be up and around the ward and allowing him to eat his usual meals without drugs or other artificial stimulation. This gives a picture of what is normally going on in the patient's stomach as nearly as it can be delineated with the patient in the hospital and with the tube

sensory change whatsoever has been produced. This leads also to the conclusion that vagus resection somehow alters the fundamental mechanism producing peptic ulceration.

Sensations of fullness, hunger or nausea are present following this procedure, according to the nature of the stimulus. Vomiting may occur if the

those described by Pfeiffer⁴⁷ in dogs following division of the vagus nerves.

We have done Graham tests before and after operation, and to date have found no distinct differences in the degree of emptying of the gall bladder.

Gastroscopy carried out preoperatively and postoperatively in Case 10 showed little alteration

FIGURE 7 Motor Activity in the Gastric Fundus and Antrum in Case 7 Ten Days Postoperatively. Little motor activity was present, and there was no response to prostigmine.

stomach becomes overdistended, from which one may conclude that the normal afferent end of this reflex arc is also intact. Smithwick^{22,48} has shown that many of the afferent pathways from the duodenum, gall bladder and biliary tract course the sympathetic nerves. The lower end of the esophagus, however, is not denervated from the sensory point of view by sympathetic ablation.⁴⁶ Nor does removal of the parasympathetic nerves at the level of this operation seem to alter sensation from the

save a decrease in reddening about the gastroenterostomy stoma.

SURGICAL TECHNIC

The surgical technic involved in this procedure will not be presented in full detail. A sizable segment of both nerves, running from the region of the lung root to the cardia of the stomach, is removed. We do this with the hope of interrupting fibers leaving the main trunks and entering the

FIGURE 8 Motor Activity in the Gastric Antrum in Case 3 Seven Months Postoperatively. The so-called "automatic" type of motor pattern is quite different from that shown in Figures 4 and 6 for preoperative patients. It was observed in this patient many months after operation and makes a striking contrast to the earlier postoperative tracings, which showed little or no motor activity. This type of tracing may represent the local response of the denervated stomach to the stretch stimulus of a balloon in the antrum, unregulated by higher centers.

lower end of the esophagus. This indicates that this area and possibly the fundus of the stomach have sensory pathways that are not yet adequately described in human beings. A possible explanation is that the submucosal plexus in the esophagus continuously carries stimuli to the upper end of the esophagus before they pass out into the main vagal trunks.

Other side-effects of the operation are relatively few. There appears to be a lowering in the calcium concentration in the blood, followed by a rise to normal, these changes possibly being related to

esophagus that might possibly become expanded in their function to take over some of that lost by sectioning the main trunks. The diaphragm is cut to permit dissection of the nerves going to the stomach and is resutured between the severed nerve ends. The proximal ends of the cut nerves are encased in one silk cylinder, pointed cephalad and sutured to the pleura, which is closed behind them in a fashion not unlike that illustrated by Dragstedt.³⁸ Although the immediate physiologic results of both his operation and ours are doubtless the same, we have performed the more extensive

cells and is not mediated in any way, either by nerves or by other hormones, so that there is no reason to expect any change following an operation in which the gastric cells remain intact

Motility

Studies on gastric motility have been carried out, and examples of preoperative and postoperative

not always long lasting, and in 1 patient waves of normal amplitude but abnormal pattern were observed eight months postoperatively (Fig 8)

Pain

Changes in pain sensitivity to balloon distention have not been demonstrated in these patients to date. With the balloons in the lower esophagus,

FIGURE 5 Motor Activity in the Gastric Antrum in Case 9 Eleven Days Postoperatively. This is a small portion of a long tracing showing a marked alteration in activity, which consists of the abolition of the large peristaltic waves.

tracings are shown in Figures 4, 5, 6, 7, and 8. These tracings have been secured by the use of an apparatus developed by Gorrell⁴³ and used extensively by Chapman,⁴⁴ which permits one to make accurate tracings of gastric waves by means of an electronic alternator and an electric motor that directs the recording apparatus in response to stimuli received from the stomach through a balloon tube. This

stomach, duodenum or jejunum, the threshold at which the patient experiences pain is correlated with the same degree of balloon distention preoperatively and postoperatively. This negative finding concerning sensory changes is of the greatest importance in evaluating the results of this procedure. In the dramatic symptomatic response produced in many of these cases, the patient awakes

FIGURE 6 Motor Activity in the Gastric Fundus and Antrum in Case 7 Preoperatively. A motor response to prostigmine is observed, which was correlated with pain. The stomach tended strongly to propel the balloon downward, and there was an unusual amount of motor activity in the fundus.

device lacks many of the faults of other apparatus for gastric kymography in so far as extremely weak gastric contractions make an adequate tracing, and as a technical device it has been most useful. The intragastric position of the tube has been checked fluoroscopically in every case, an essential precaution since fundal activity is normally rather low.

The typical result produced by vagus resection in the early postoperative phase is the complete abolition of large gastric contractions. This is correlated with the change produced in the x-ray films, previously mentioned. There is a lessening of peristaltic activity. This effect is apparently

from the anesthesia stating that he feels that his ulcer has been cured or that he feels so well that he would never have known that he had had an ulcer. Such relief brings to mind the possibility that sectioning the nerves has simply anesthetized the stomach and duodenum so that the pain from continuing ulceration is not felt. The evidence against this conclusion, however, is overwhelming. The rapid healing of the ulcer, as well as the secretory changes, strongly suggests that a more profound change than anesthetization has been produced. Sensory studies demonstrate not only that the area is unanesthetized but that apparently no

AN INTERVIEW METHOD FOR OBTAINING PERSONAL HISTORIES*

CLARK W HEATH, M D †

BOSTON

IN MEDICAL practice, knowledge of the patient's personality and social history is often essential for diagnosis and treatment. There is great need both in practice and teaching for well organized methods of obtaining this information. The interview is a powerful instrument if properly employed, yet most students and physicians have received little training in the art of interviewing.

In recent years I have had personal experience with a short-interview method for the selection of officer candidates. This method, prepared by Woods¹ and designed to reveal pertinent facts regarding the man's capacities, interests, personality traits, weaknesses and strengths, does not employ an elaborate technical terminology and does not require psychiatric training. After a brief period of practice most interviewers who had an earnest interest in the variations of human personality could reach pertinent conclusions in the majority of young men examined. It seemed obvious that such a formalized, brief interview could be profitably employed as a means of obtaining the personal histories of patients. I have used some modification of it for most of my private and hospital cases during the last several years, and the experience thus gained has convinced me that an interview of this sort should be a part of the medical history.

The use of the interview embraces not only a certain technic but also a definite point of view. To illustrate this, 3 cases of borderline rheumatic fever in young adults will be cited. The histories and physical examinations were all much alike. There had been fatigue, malaise, probably some fever, and migrating joint pains. The fourth-year medical students, acting as clinical clerks, were quite properly concerned with the sizes of the hearts, systolic murmurs, temperature charts, white-cell counts,

sedimentation rates and electrocardiograms. In each case, brief questioning, following the plan of the interview, revealed within a few minutes some of the crucial facts needed for adequate understanding and handling of the illness.

The first patient was a high-school girl of sixteen years whose chief enthusiasm was for roller skating, in which she was possibly headed for a professional career. All her extra time and money were devoted to this absorbing interest, and she allowed herself only five or six hours of sleep. The second patient was a high-school boy of seventeen, whose history was much the same except that he was exclusively concerned with jive dancing. The third case revealed a more complicated personal history. The patient was a robust girl of seventeen who had been obliged to leave school two years previously because of the death of her parents and consequent financial restrictions. She lived with her grandparents, who assumed the role of Fagin. A brother was frequently confined in a mental hospital. The girl worked in a defense factory in the daytime and as a restaurant waitress in the evening, traveling for an hour by trolley between her places of employment. Her chief desire was apparently to receive a nurse's training, but this plan had to be indefinitely postponed because of the lack of a high-school education and the necessity of supporting her grandparents.

Obviously, the most important element in each of these cases was common to all — namely, abuse of the human machine, late hours and lack of sleep. Each patient required a somewhat different approach to correct the poor hygiene, necessitating a personal knowledge of the patient and mutual understanding between him or her and the physician. The medical students seemed to have missed this point, their training had not covered adequately the palpable relation of the social and personal history to the etiology of disease.

The term "personal history" covers a wide area. It is not sufficient to understand merely the tenets of psychosomatic medicine, as is illustrated by the

operation for the reasons outlined in the introductory section of this paper

DISCUSSION

The place that this operation will ultimately occupy in the surgical armamentarium is at present not clear. On the basis of our present limited knowledge and experience with the operation, little can be said concerning its limitations. It is clearly not indicated in acute perforations, acute massive hemorrhage or advanced cicatricial obstruction. These three situations should be dealt with by appropriate surgical maneuvers other than vagus resection. Beyond these obvious contraindications, we have not yet found criteria by which patients can be excluded from the possibility of benefit from this procedure.

The occurrence of bleeding in the past is no contraindication to the operation.

Gastric ulceration proximal to the pylorus should be approached with the greatest caution so far as this operation is concerned. The reason for this is that although the diaphragm is open, the region of the ulcer cannot be adequately visualized and palpated, and even if it could be, it is often impossible to differentiate ulcer from cancer. Resection should therefore usually be employed in such cases.

Patients who have had other surgery, such as pyloroplasty, posterior gastrojejunostomy or gastric resection, and who present themselves with renewed ulceration are ideal subjects for this procedure. The previous surgery does not in any way complicate the operation, and it may be carried out with excellent relief of symptoms in cases in which renewed attack on local structures through the abdomen would be technically complicated, with the end result open to question.

The largest group of cases in which this procedure seems to be of value is that of young or middle-aged men with a long history of peptic ulceration, possibly with previous perforations or hemorrhages, unobstructed and not acutely bleeding, who have been refractory to careful medical therapy and who have severe ulcer pain in times of stress,⁴⁸ which can be relieved transiently by the usual antacid, milk or food. This type of patient, in our experience, obtains a uniformly good result from this procedure, but the duration of the relief is at present unknown.

SUMMARY AND CONCLUSIONS

The background and rationale of transdiaphragmatic resection of the vagus nerves for peptic ulcer is discussed.

This operation has been performed on 15 patients, and the clinical results in the first 12 cases are briefly discussed.

The general nature of the physiologic changes as regards secretion, motility, x-ray emptying and

afferent conduction follow a fairly consistent pattern and are described.

The operative maneuver employed is a trans-thoracic transdiaphragmatic resection of both vagus nerves in which a sizable portion of nerve is resected and steps are taken to avoid regeneration.

This procedure appears to be a potent weapon in dealing with peptic ulceration, as judged by clinical results in these early follow-ups.

The final value of this method must await the passage of time and careful study of the patients operated on at this and other clinics.

It is hoped that radical transdiaphragmatic resection will avoid the return of the ulcerating tendency, which stands as the chief obstacle to the success of this or any other operation for peptic ulcer.

sequent topics such as athletics, activities and interests and the choice of a career. Particular interests and abilities are easily elicited through the patient's choice of subjects and his liking for or dislike of particular courses.)

A Scholastic

How old were you when you left school?
How far did you get in school?
What high school (college) did you go to?
Did you like it there?
What subjects did you like best?
What did you major in?
Why did you choose that field?
Did you do all right in mathematics? (English, etc.)

B Extracurricular Activities (The choice of a field of specialization in college may lead naturally to a choice of lifework. If so, the following questions may be deferred until later.)

What did you do outside of courses in school (college)?
Did you receive a scholarship?
Did you have to earn some of your way?
Did you go out for a school paper? Glee Club?
Special organization?
Did you hold any offices?

III Activities and Interests (The examiner should strive to get an estimate of the patient's muscular co-ordination and ability to withstand strenuous exercise.)

A Athletic Activities

Did you spend much time in sports?
What sports do (did) you take part in?
What was your best sport?
Were you on a varsity team?

B Spare Time

What do you do in your spare time?

C Outdoor Life

Do you like outdoor life?
Do you swim? Fish? Hunt? Sail? Ski?
What experience have you had in hiking? Camping?

D Summer Activities

What do you like to do summers?
How do you like to spend vacations?
What did you do last summer?

E Artistic and Special Abilities

Have you any special hobbies?
Do you play a musical instrument?
How much training have you had in this?
Do you sketch or draw?
Do you like to read?
What books or magazines do you like to read?
Are you handy with tools?
Do you drive a car?
Can you repair it?

F Social Activities

Do you have many close friends?
Do you find it easy meeting new people?
Do you prefer to do things with people?
Do you and your wife dance?
Do you play cards?

IV Family Life

A Boyhood Home

What was your father's occupation?
What was your father like?
Did your mother have an occupation outside of her home?
Were you close to your parents?
What about your brothers and sisters?
What are they doing now?

B Married Life

How old is your wife?
Where was her home?
Does she enjoy housework?
Does she have interests outside of the home?
How long did she go to school?
How many children have you?

What are their ages? Sexes?

Do they ever get on your nerves?

How do you and your wife spend the evenings?

Are you and your wife of the same religion?

How do you get along together sexually?

V Religion

What is your religion?

Were you brought up in this religion?

Do you belong to a church?

How important is your religion for you?

Do you enjoy ritual?

Do you send your children to Sunday school?

VI Occupation (The manner of choosing a career and the motivations that impel a man in his work are sometimes the richest source of knowledge concerning him. The opportunity also may be taken here to determine the actual duties at work, so as to discover possible occupational hazards and strains bearing on the illness.)

What is the nature of your work?

How did you get into this field of work?

Does it satisfy you?

Do you get along well with the people there?

Where do you think your abilities lie?

Do you seriously consider some other field (teaching, law, business, etc.)?

What are your plans for the future?

VII General Habits

What time do you usually get to bed? Get up in the morning?

Do you smoke? Drink? Take any medicines?

Are you naturally orderly with your things?

What do you usually do when you get home at night?

VIII Mood (Minor mood swings, without necessarily being pathologic, are frequent, and are sometimes responsible for unexplained variations in efficiency. Moreover, the mood in some persons seems to be set at different levels — some being naturally warm and optimistic and others depressed and pessimistic.)

Do your spirits run on an even keel?

Do you run into periods of a week or so in which you are not so efficient, or do not feel so well?

Do you have any trouble in controlling your temper?

IX Stability of Autonomic Functions

Does it affect you to have to speak in public?

In college were you affected by examinations? Games?

Are there any particular stresses that cause symptoms?

Does anything interfere with your sleeping? Eating?

Does anything ever produce diarrhea? Frequency of urination?

X Over-All Judgment of Personality and Recording of Personal History

The judgment of the patient's personality* is made from the interpretation of the answers to the above and similar questions and from the appearance, manner and expression. The personal history may be recorded in simple language, since it bears on the complaints and the medical diagnosis in question. A good deal could be said for placing it as a preface or foreword to the formal medical history.

*No attempt is made to suggest a formal personality classification. For the purposes at hand it seems best to describe patients in words of everyday language such as "dependable," "reliable," "likable," "mature," "well-mannered," "straightforward," "cheerful," or their reverse "an energetic, hard-headed businessman," "a neat, precise rather sensitive individual," and so forth. Some attempt should be made to record what in the opinion of the doctor is the strength of the material the patient is made of: that is, is he basically sound, invulnerable and well-integrated? Are his problems the result of circumstances or relatively self-conditioned? Description of the person naturally seems to divide itself into constitutional and basic traits more environmentally conditioned or temporal traits such as education, career choice and manner of life and environment, including family, friends and physical conditions. These factors may be recognized to form a system, each playing a role and impinging on the nature of the illness and the therapeutic indications. A discussion of personality classifications will be found elsewhere.^{6,7}

many authenticated cases of the relation between mind and physiologic function. Before these factors can be adequately evaluated, there must be an understanding of the patient as a person and of his environment and systematized knowledge concerning not only the relation between mind and body but also that concerning personality and its role in the environment. The present report has to do with the latter and is necessarily only an introductory statement. The term "personal history" embraces not only the personality but the social history, as incorporated in medical-history forms, as well as some part at least of the traditional items in the family history, marital history, occupational history and habits.

GENERAL ASPECTS OF THE INTERVIEW

The task in obtaining the personal history is not only to acquire a working knowledge of the personality of the patient, his activities and interests and his environment but also to establish a satisfactory physician-patient relation so that immediate therapy and future handling of the case will be facilitated. Much has been written about this sort of approach, which is the very core of the practice of medicine. Monks² in a pertinent article written in 1939 drew on the experience of Roethlisberger and his co-workers³ for practical suggestions in the technic of interviewing. The latter have pointed out that the interviewer is in the role of a listener, who "should listen not only to what a person wants to say but also for what he does not want to say or cannot say without help." A book by Bingham and Moore,⁴ entitled *How to Interview* gives excellent material for the technic of various kinds of interviewing and describes their dangers and pitfalls.

The interview is appropriately a part of the medical history. Brief questions are asked, giving the patient the opportunity to expand his replies. The approach is clinical, but it differs from that of the rest of the clinical history in an important respect. Whereas the usual clinical approach is to explore the range of possible diagnoses, the purpose here is to reveal positive traits and capacities and to discover what the patient does and likes to do and the nature of his background and adjustment, his way of life and his occupational and cultural environment. Some reorientation is necessary in the physician's thinking in acquiring this kind of information, for his training in history-taking, particularly if he has just completed his medical-school and hospital training, has been largely in the direction of identification of disease. The personal history serves a double function, since disabilities and defects inevitably come to light in the course of a well handled interview, and their nature can be pursued by appropriate questioning. Nevertheless, the main intent of the personal history should be to learn "the whole nature of the man within the patient."⁵

The physician should have either in mind or close at hand on paper a suitable outline of the kind of information he wishes to obtain. This varies somewhat, depending on the patient's age, sex, intelligence and cultural background. Competent interviewing is an art that is developed by experience. It is materially aided by a pertinent and thorough plan of the field to be covered. A suggested outline of topics and appropriate questions is given below.

It is a mistake to follow rigidly any definite order of questioning. Certain questions strike home in certain patients who, if they believe that they have a sympathetic listener, describe conditions of their life that are extremely revealing. In such cases, the order of the interview should be dropped for the time, the patient being allowed to pursue the point in question until the examiner is satisfied that a satisfactory understanding of the situation has been reached. The physician should be constantly alert to such possibilities. Here, as elsewhere, the advantage of the clinical method lies in its flexibility and its adaptability for different persons and changing circumstances. It has been observed that one must listen not only to what the patient says but for what he does not say. Often it is the manner in which a question is received and answered that is of importance rather than the actual content of the answer. To adopt the expression of Woods,¹ "The interviewer must depend upon the astute use of all his senses rather than upon systematized appraisal of question and answer." Diagnosis in this field has not advanced nearly so far as has the recognition of classified somatic disease. Nevertheless, even in the latter field, reaching a diagnosis is often somewhat more of an art based on broad experience than it is a technic.

OUTLINE OF INTERVIEW.

The following list of suggested topical headings is necessarily only tentative and is not to be rigidly followed. Limitations of time and the particular circumstances of the patient alter the pattern. The questions listed under the various topics are merely introductory ones, and should be altered to suit the circumstances. They comprise those that seem likeliest to elicit revealing answers. Answers that are suggestive should be pursued by questions of a like nature. For the purpose of illustration, it will be assumed that the patient is an adult man who has had a college education, is married and has held a job for a number of years. Questions inappropriate for the person who has not attended college, for the single person or for a younger man will naturally be eliminated, and others may be substituted.

- I *Appearance and Expression* (At the start a mental note is made of such items as general appearance, body build, dress and temperature and moistness of the hands, and throughout the interview expressive movements and the manner of speech are observed.)
- II *Education* (The educational history offers an easy approach to the interview. It naturally blends with sub

A Good, and we have found use for it I bought a single-family house five years ago Had a setback on it a couple of years ago and I had to mortgage it, but since then things have gone easier Still paying on the mortgage

Q What is your actual income?

A Basic income from school is \$4000 with the emergency allotment. It would be about \$3880

Q Do you have a car?

A Yes, I own a car and drive it

Q Do you feel you had to work this summer?

A I felt I wanted to after buying this cottage — a duplex The income from the one half will more than take care of the other once I get by this primary arrangement

Q But you could have gotten by without working?

A Yes

Q What do you do with your spare time?

A We lead a rather quiet life We have five children, the last was born just last July Haven't had too much occasion to get out and do things We get along rather nicely, but we don't have activities programmed out We have many friends, and although we haven't been going many places because of my wife's condition, we are not antisocial, and when time permits, we visit.

Q Do you and your wife play cards?

A We play when we have to, but we don't have time

Q Do you read much?

A. Not much [Named two current magazines] Nothing much Of course, I read a good deal in my line of work I study everything for accounting and teaching, but I like fiction

Q Listen to the radio?

A Yes, but not too much

Q Ever go dancing with your wife?

A. Yes, on occasion, but there are few lately I'm an emotional cuss, I guess I wouldn't be happy if I didn't push myself My wife recognizes this, and tries to restrain me only to a certain extent

Q Do the children get on your nerves?

A Yes, very much at times But you love them just the same. We really get along very well They are sore at me right now for not coming home I'll have to fix that up

Q What is your religion?

A. Catholic.

Q About how strong is the influence?

A. Strong influence, devoted to the church and go regularly Follow the religion

Q And the children?

A We raise them accordingly

Q Are the children doing well in school?

A. Very bright, the oldest is just past 5, started last year in kindergarten and is in the first grade this year We were told that he was one of the best down there. The girl following him is in kindergarten now We had our fifth youngster in July

Q Has there been anything in college or school such as examinations which got you upset?

A Maybe in the beginning, but not so much later I try to divorce the idea of confidence from conceit. I feel I have something that I should not be afraid to approach anybody on There were some times when I got gas and used to shiver

Q What symptoms did you notice when you were young?

A. Sour stomach and gnawing at night.

Q Any effect on the bowels?

A. No

Q Did you think it affected passing water?

A The frequency of the passing of water increased

Q Did examinations bother you?

A. No, I would get keyed up, but no more than the average person Might find that perhaps I was not ready for it, but normally I took it as it came along except for the usual emotional stirring up that everybody gets

Q When you are nervous, do you smoke more?

A Yes, this is one of my big weaknesses Don't care much for cigars, especially what they are handing out these days [He smokes six or seven cigars a day]

Q What about eating?

A I eat fairly fast

Q Now, you sleep well, do you?

A Yes, prior to this little disturbance now Within the last 2 months I have been waking up nights I have had the vision of this thing coming on Guess it's because I'm a teacher I can understand my situation I figured on this particular situation With the type of operation I had, I knew it was not one that would be a permanent one with me, particularly since my sister, who had a complete stoppage 2 years ago, had the more recent type of operation in which they removed two thirds of her stomach I thought it would come to me

The interviewer in this case spoke less than one fifth of the time The questions kept clear of strictly medical symptomatology and were directed toward what the patient did, could do and liked to do, how he conducted his life, what his interests were, and to some extent the influence of his way of life on his bodily functions The interviewer was not under the necessity of making a psychiatric diagnosis An academic classification of the personality would have been of accessory interest The problem was the simple one of determining what factors in the patient's life had to do with his illness, the better to advise him and to arrange conditions to help him to live with health and comfort

Advance in knowledge of the psychosomatic field may clarify such an approach, but the problem must always remain that of getting to know the patient and his environment in order to treat him more effectively There is need for adequate classification in this whole area so that the usual social and personal factors bearing on particular illnesses may be more easily recognized The particular point considered here, however, is the technic of interviewing, so that it is preferable to describe the patient in simple, nontechnical language In the case just cited the personal history might be recorded somewhat as follows

This is a tall, rather heavily built, dark-complexioned man who is very co-operative and talks rapidly He shows little anxiety He is a college teacher of accounting and the father of five children On the side he does real estate work His religion is Catholic, but he does not seem to be deeply devout In fact he has no great depth of thought He is intelligent, pleasant, energetic but without many resources within himself He is happiest when he is on the go He says that he leads a quiet life, yet his fifth child was born recently, and his real estate ventures outside of an active career of teaching give him no leisure Perhaps his restlessness is related to his poverty in his youth and the necessity to seek financial security, which seems to be a strong motivating force in his life He has many strong basic qualities, such as reliability, dependability, persistence and conscientiousness He is rather simple, accepting life as it comes, and yet is not unaware that his periodic gastrointestinal illnesses are in some way linked with his continuous, restless activity One has the not unfamiliar impression of a man of affairs restlessly pursuing his career at fast tempo — hardly an ideal way of life for the patient with peptic ulcer and one that quite likely can be of etiologic significance

The patient was convinced, before the discussion took place, that he should receive partial gastrectomy particularly since a sister was apparently treated successfully in this manner He believed that he could thus continue symptom-free and

The simple factual material may be recorded as usual in the traditional medical-history outline, under headings such as "Family History," "Marital History," "Social History," "Occupation," and "Habits." A chronological handling of the personal history is often of value, for it may illustrate the sequence of events or repetitions of them that bear on the present illness. If the statement is sufficiently descriptive, it will serve as a personality judgment itself and will be of some prognostic significance.

In respect to women patients, suitable alterations of the questions listed above will suggest themselves. The lifework is usually of lesser importance. Family life, social life and interests, and abilities in the household arts are among the more profitable topics to pursue.

A TYPICAL CASE

The following is an abbreviated account of an interview with a patient suffering from a bleeding peptic ulcer, recorded verbatim. It will be recognized that liberties have been taken with the above outline, for brevity's sake only the most pertinent facts being included. Taking notes is not an ideal method, and it is often difficult to recapture the feeling of the interview through the written record. The interview illustrates, however, the simple, direct method of questioning following a plan. The patient was quite willing to discuss at least the superficial activities of his daily life and some of his accomplishments and aspirations.

L. H., a 39-year-old, married schoolteacher, was admitted to the Medical Ward on September 8, 1944. Symptoms of peptic ulcer had been noted since he was 20 years of age. At 22 years, he was operated on for so-called "perforated duodenal ulcer." At 29 years, there was an episode of weakness and black stools. At 33 years, there was a severer attack of bleeding, with hematemesis. Bleeding occurred a third time at 37 years. During the 2 months previous to admission the patient had eaten irregularly, and for the last 5 days he had felt weak and tired. Three days previously, he began to pass tarry stools. A sister had peptic ulcer, which was operated on, apparently successfully, by partial gastrectomy. The patient desired this operation for himself, hoping to return to his customary activities.

Physical examination revealed a tall, heavily built man, pale but in no discomfort. Examination was otherwise negative. The red-cell count was 3,050,000, the hemoglobin 56 per cent and later 45 per cent, and the hematocrit 26 per cent. A blood smear was negative except for hypochromic red cells. The urine was normal. The nonprotein nitrogen was 45 mg per 100 cc. and total protein 5.5 gm. A blood Hinton test was negative. Gniac tests of the stools were strongly positive.

The interview was as follows:

Q. How much schooling have you had?

A. I had my public-school training at ——— High School and then worked for 4 years. There is where I made my first mistake, but it turned out all right. After working for 2½ years I started with evening courses at college. After 1½ years of that I dropped the day work and went to college as a regular day student.

Q. How old were you when you finished high school?

A. Sixteen when I finished high school, 17 shortly afterward.

Q. When did you finish at college?

A. January, 1927.

Q. Did you have to earn your way through college?

A. Just my board. My father died when I was an infant. My mother kept the family alive. She's still living.

The decision which I made to return to college was influenced by the decision of the family.

Q. Did you engage in extracurricular activities while in college?

A. Yes, I was elected two years running to fraternities, but I did not have much time.

Q. What about sports?

A. I liked them, but never participated. Never seemed to have time, except for sand-lot activities. I was really very busy all the time due to family circumstances.

Q. Did you get good marks in school?

A. In high school I "slowed off" as I was working after school and had no thought of going on to college. Did fair work in high school.

Q. What about camping and outdoor activities?

A. None, except last summer I had a cottage at ———, where there were ample facilities for such things, and I thought my wife and I could have a lot of fun out there. I expect to buy a sailboat or motorboat.

Q. Do you like that sort of activity?

A. Yes, and the youngsters would get a kick out of it, too.

Q. Are you mechanically inclined?

A. No, I'm not mechanically adept.

Q. What about musical activities?

A. I started on the violin, enjoyed music, but I haven't had the time to go into it too much. I've done some tax work for several musicians in an orchestra and thought I should look into whatever it was that made them so interested.

Q. What were your plans after high school?

A. I went to work at the American Telephone and Telegraph Company when I left high school.

Q. You were thinking of something in business?

A. Yes, I was there for at least three years. Then I resigned from there to go with Procter and Gamble. I was disappointed there and would have been far better to remain with the telephone company.

Q. Any degrees from college?

A. BS and M.A. degrees from college. I did much better there than in high school.

Q. When did you start teaching?

A. I started to teach there. Professor ———, head of the ——— Department, started me teaching. He was more or less of an inspiration to me and brought me into the ——— Department as his own corrector, and my last year there I was an assistant instructor, and then following that they sent me to the University of Puerto Rico to teach accounting.

Q. Did you go to Puerto Rico?

A. Yes, I taught one academic year, about 9 months, teaching bookkeeping and accounting there, then I came back here to teach.

Q. Do you think your abilities lie there?

A. I do seem to feel that in general I have been able to get along very well with people and don't have very many enemies that I can think of. One examiner in the Boston schools said I was a born salesman. I have perhaps brought that up a little bit by my side activities in real estate.

Q. What were these side activities?

A. I set up desk space over in ———, a real estate office. Because of my teaching course I would not be there in the daytime, but I managed more or less to work into the real estate activity.

Q. Did you like it?

A. I don't know whether I would like it as a full-time venture. The head of it spoke to my wife and said I learned more about it in a year than most people do in fifteen or twenty years. Perhaps that's because I was interested in it as a side venture.

Q. Have you been successful in selling in that sort of field?

A. I have. For example, I just went in there more or less to maintain my desk space that summer, and before I officially closed my season, I sold three or four houses. The next year I doubled my sales, but this year I didn't do so much on account of my illness.

Q. What is your family income?

problem more quickly resolves itself into one of adjustments or of personal hygiene. Garrulous and uerulous patients are of course encountered. In such cases time and patience are most needed, but one may be helped by dropping a subject and going on to one of equal interest to the patient. Patients vary in the orderliness of their answers, yet they nearly always care for the physician's time, particularly if they recognize his genuine efforts to try to help. Most patients are honest and describe symptoms, worries and fears that are real to them. It has perhaps been overemphasized by psychiatrists that illness is sometimes a means of avoiding unpleasant situations, but it is rare to find definite proof of this mechanism. Perhaps, like hysterical episodes, it has become less frequent than formerly. Today the social and personal concomitants of disease seem to come under the heading of satisfactions and dissatisfactions — in other words, adjustments. Successful interviewing requires a spirit of trust in the patient. At the same time, if the physician will take the time to delve into the positive qualities of good, he will find a most helpful adjunct to his success in the practice of medicine.

SUMMARY

A method of short interviewing for obtaining personal histories is outlined. It consists of short, pertinent questions, covering the positive qualities,

activities and environmental relations, the patient being given an opportunity to talk freely. Examples of questions and a sample interview are given.

It is believed that an adequate personal history should be a part of formal medical history-taking. Students should be thus instructed.

The lack of adequate attention paid by medical teachers and practicing physicians to the more general personal and environmental facts of patients' lives is related to the one-sided development of technical knowledge and specialization, symptomatic of the times.

pursue his accustomed mode of life. One wonders, however, what would be the ultimate effects of such a strenuous life apart from the success of the gastrectomy. Up to nine months postoperatively this patient was free of gastrointestinal symptoms, and he had managed to free himself of many of his outside activities.

* * *

The concept of the physician as friend and adviser of the patient goes back to ancient times. The point of view has been expressed well by modern writers.^{8,9} There is nothing new claimed for the material presented here, including the interview method itself. Many physicians with experience in general practice recognize the importance of a personal knowledge of the patient, and they have developed their own technics for managing the patient in some manner analogous to that described. It is therefore surprising that the study of personality and environment forms such a small part of the teaching of medicine. It is as though this teaching were planned to train students for only half their probable duties as physicians—the more technological duties. The physician cannot confine himself to his technological last without harming many patients. Looking at the matter from a broader point of view, one gains the impression that the concentration of medical curriculums on the more specialized branches is symptomatic of what has been occurring in the world outside of medicine. Mayo¹⁰ writes

He is an inveterate optimist who is not sobered by a comparison of our own time with the high expectations of a century ago. In no area of activity have nineteenth-century expectations been disappointed. But privation and strife have not vanished from the earth. *While material efficiency has been increasing for two hundred years, the human capacity for working together has in the same period continually diminished.*

Perhaps the capacity for working together has not changed so much, but the conditions that affect it have altered greatly. The human capacity of physician and patient for working together has been affected by the tremendous growth of specialized knowledge in the medical sciences. There are few physicians who will deny this, yet disproportionately little interest is being paid to this essential aspect of medicine. Little enough is known in this area, at least compared to the body of established fact in physiology, pathology, bacteriology and the like. Medicine could benefit in this direction by closer contact with some of the other disciplines concerned with the welfare of people, such as physical and cultural anthropology,¹¹ clinical psychology, education and the social sciences.

A step toward the desired goal would be to introduce as a required part of history-taking an adequate survey of the personal facts about each patient. This would not only be of educative value to the student but would also inevitably direct

closer attention to the gaps in one's knowledge of people. Through interested teachers a body of data could be accumulated for investigative purposes that would allow medicine to contribute a greater share to the knowledge of personality and environment and their relation to the total social scene.¹²

This approach is not without therapeutic value. All patients naturally have a primary interest in themselves and their affairs, and most of them are ready to talk if the circumstances seem appropriate. They often have no one with whom they can discuss their problems. Unfortunately, many believe that most physicians are interested only in such factors as physical examination and physiologic mechanisms and tests. Many patients show some insight into the personal or environmental side of their illnesses, which may be the seed for better self-understanding. It is well known that the latter may come not so much by direct advice from outside as by a kind of self-education from within. Traditional medical history-taking searches for what is wrong. A better balance and a more agreeable approach for the patient are brought about by the addition of the personal history, which emphasizes not so much what is wrong as what are the positive qualities. Medical case histories if taken at their face value paint dismal pictures. The pessimism that they depict is not thereby closer to the truth.

The personal interview helps to decide the occasional question as to whether the matter might not be better handled by a psychiatrist. But most patients do not need a psychiatrist, advantageous as this might be. The friendly counselor, which the physician should be, is quite as competent as the psychiatrist to handle the large proportion of problems presented by private patients, and he is sometimes more so. Many psychiatrists freely admit this. Moreover, there are not enough psychiatrists to care for the large numbers of patients who have symptoms not referable to organic disease. The essential point is to know when the psychotherapeutic problem can be better and more safely handled by the specialist.

There have been certain objections to proposals for spending time and effort in exploring the personal history of the patient. Many physicians fear to encroach on areas of an intimate nature, but most patients readily understand what the physician is driving at in the interview. Involved questions may arouse a fear that the physician has mental disease in mind, but this fear is dissipated by simple questions about school, choice of work, family, friends or some point the patient himself has raised. On the other hand, if mental disease is present, the problem must inevitably be gone into.

The question of time-saving is always an important one. In the majority of cases there is actually a large saving of both the physician's and the patient's time. Useless referrals and unnecessary tests and appointments may be avoided when the

Since there was likelihood of further air raids, with subsequent difficulty in controlling the patient, it was decided to evacuate him to a hospital in a quieter locality. At about the time the patient was scheduled for evacuation, 4 days after the atropine dosage, he suddenly became alert and rational. When he learned that he was to be evacuated, he said that he remembered nothing of his activities during the last 4 days. When told something of what he had done, he apologized and asked that he might remain in the hospital rather than be evacuated, since he wanted to return to duty with his own organization. He was amenable to all forms of treatment. Later on the same day he first began to show slight sweating of the skin and his pupils began to react lightly to light.

On the following day, psychiatric examination showed good rapport, with normal emotional responses. There was no evidence of delusional thinking or hallucinations, in fact, the latter were not reported at any time during the psychotic episode. The patient showed complete insight into his previous paranoid delusions. He stated spontaneously that during the active period of the psychosis he had aroused momentarily, realized that his thinking was abnormal and then lapsed into his previous state without being able to help himself. There were moderate sensorial defects — that is, in orientation, recent memory and simple calculations.

The following information concerning the patient's background was obtained. He was an average, outgoing youngster, the sixth of 11 children. Throughout his schooling, which took him through the ninth grade, a year in the Civilian Conservation Corps, 2 years of steady work in a coal mine and his period of service, he was sociable, athletic and extroverted. The family relationships were normal. His direct antecedents showed no neuropsychiatric abnormalities. Both by history and by direct observation the patient's total personality development was the polar opposite of paranoid.

During the next 3 days, the patient was kept under moderate sedation with phenobarbital. In spite of the fact that there were other air raids, he was calm and composed during each one, showing no tendency to become maniacal or even excitable. The pupils became smaller during this time, approaching normal size 7 to 9 days after he had been given the atropine. He also noticed that his power of accommodation improved.

On November 1, the patient felt perfectly normal. He was re-examined neurologically and psychiatrically. The psychiatric examination showed continued complete insight, and rapport and sociability were above average. The sensorial defects previously noted had entirely cleared. General comprehension was good, arithmetical reasoning fair,

understanding of similitudes and contrasts good, memory for a story in one paragraph good, and vocabulary fair, and he was able to repeat eight digits forward. Intelligence was estimated as low normal, and the defects previously noted were therefore regarded as significant and as related to the toxic action of the drug.

The neurologic examination was also normal except for slight hypesthesia over the distribution of the right saphenous nerve. At the height of the acute psychotic episode the patient had received a contusion on the inner aspect of the right thigh. It was believed that this explained the slight subjective sensory abnormality of the right saphenous nerve. The patient was discharged to duty 2 weeks after the onset of his illness. He was normal in every respect and anxious to return to his old assignment.

SUMMARY

A case of severe poisoning following the ingestion of 10 gm of atropine sulfate is reported. The patient made a complete recovery in two weeks. This was punctuated by a brief but violent psychotic episode, consisting of confusion and paranoid delusions, in a person of basically normal personality makeup. The psychiatric improvement was concomitant with the first signs of sweating of the skin and reaction of the pupils to light. When discharged to duty, the patient showed perfect insight into his previous toxic psychosis.

CLINICAL NOTE

ATROPINE POISONING

REPORT OF A CASE, WITH RECOVERY AFTER THE
INGESTION OF ONE GRAM

CAPTAIN EBEN ALEXANDER, JR, MC, AUS,
MAJOR DONALD P MORRIS, MC, AUS, AND
RALPH L ESLICK, P A SURG (R) USPHS

THE effects of atropine when given in therapeutic doses are dramatic. When it is given in doses that may cause poisoning, the results are sometimes extremely serious or even fatal. The exact incidence of such poisoning is not known. Deaths from this cause constituted an extremely small percentage of those from poisoning in Massachusetts from 1928 to 1937 — considerably less than 1 per cent.¹ There are several reports of cases of poisoning and of recovery with doses of atropine varying from 0.4 to 100 mg.²⁻⁷ In each of these cases the reaction followed a distinct pattern, the differences between the cases being one of degree rather than of variability of reaction. The largest dose of atropine given with subsequent recovery is apparently that reported by Comroe,² whose patient received 0.5 gm by mouth.

In several of the cases mental disturbances were evident.^{3-5, 7} These consisted of transient confusion and visual hallucinations. The patient in the present case, on the other hand, showed confusion and paranoid delusions, without visual hallucinations. His behavior was also much more violent than that of the others. This difference may be related to the large dose.

In view of the fact that this patient received twice the maximum dose previously reported, and in view of the differences in the psychotic reaction, it is believed that a summary of the clinical course will be of value and interest.

CASE REPORT

A 23-year-old man of Polish extraction complained, on October 22, 1944, of severe abdominal pain, which necessitated calling the medical officer. The officer had seen him 6 months previously when he had a similar attack of abdominal pain. At that time he was sent to a hospital, where he recovered completely without benefit of operation or special x-ray examination. The appendix had been previously removed. He returned to duty and performed his duty satisfactorily until the reoccurrence of the abdominal pain.

At examination the abdomen was held somewhat rigidly, but there were no masses and there was no localized tenderness or spasm. The medical officer administered 16 mg of morphine sulfate subcutaneously and instructed his assistant, an enlisted man, to give 0.4 mg (1/150 gr) of atropine sulfate but the latter through error gave 10 gm (15 gr) of atropine sulfate by mouth. This was contained in a small

ampul (Merck — Atropine Sulfate, U.S.P. Powder, 40's). There was no doubt that the patient consumed the entire dose, and he was not seen to vomit at any time after its ingestion. The size of the dose was well attested to by the medical officer in charge, who later brought to the hospital an ampul of atropine sulfate exactly similar to the one that had been given to the patient.

Within a short time the patient began to feel hot and flushed and complained that he could not see well. In the course of the next 2 hours, he became stuporous and difficult to arouse. Two hours after he had received the atropine, the stomach was washed out with a weak solution of potassium permanganate. During the next 24 hours the patient became comatose, the pupils dilated widely and were not responsive to light and the temperature rose. The respirations became increasingly slow and shallow, and at the end of 24 hours were so shallow that the patient appeared not to be breathing, but the pulse remained rapid and regular. He was given supportive therapy, including 5 per cent dextrose in 2000 cc of water, and showed some improvement, and was then transferred to an Army evacuation hospital in an extremely critical condition.

The temperature was 104.2°F, the pulse 110, the respirations 20, and the blood pressure 101/60. Physical examination revealed a well developed and nourished man in a stuporous state who reacted only to very painful stimuli. The skin was extremely flushed and hot and perfectly dry, with no cyanosis. The heart, lungs, abdomen and extremities were normal. On neurologic examination, the pupils were extremely dilated and did not react to light. There was a bilateral external strabismus, and the eyes were not attracted by a moving light. The fundi were normal. There was no facial weakness. There was slight but not marked stiffness of the neck, with a mildly positive Kernig's sign. The deep tendon reflexes were bilaterally diminished but equal. The abdominal reflexes were diminished, and the cremasteric reflexes were equal. The Hoffmann sign was normal bilaterally. The Babinski and Chaddock reflexes were unequivocally positive bilaterally.

A spinal puncture was done, with the following normal findings. The initial pressure was equivalent to 160 mm of water, and the cells were not abnormally increased. No facilities for determination of the protein or gold-sol curve were available.

Within 1 hour of admission, or 30 hours after the atropine was given, the axillary temperature was 105.2°F. Alcohol sponge baths reduced the temperature to 102°. Two thousand cubic centimeters of 5 per cent dextrose in water was given by vein and during the next few hours he voided several times, each time using the urinal. He was not incontinent. The urine showed no abnormality except for the presence of sugar, which was accounted for by the dextrose received by vein. Subsequent examinations showed no sugar.

On October 24, 40 hours after the dosage of atropine, the patient began to react. He knew his name but did not know where he was or the date. The temperature was 99.0°F, the reflexes were normal, and the Babinski and Chaddock signs were negative. The pupils were still widely dilated and showed no reaction to light. The patient was unable to accommodate his vision. There was no sweating.

On October 25, the patient was apparently improved. He was tremulous but co-operative and seemed rational. The temperature and reflexes were normal. He was restless and was given mild sedation with phenobarbital. In the evening of this day, during an air raid, he suddenly became maniacal, began to scream, stripped off all his clothes and ran about the hospital. He was restrained with great difficulty, and was sure that all those trying to return him to his bed were his enemies and were trying to harm him. He did not recognize the ward officer. He was given 0.5 gm of sodium amytal intravenously, almost without effect, and an additional 0.5 gm was immediately given. This induced normal sleep. Six hours later he again became extremely restless and it was necessary to repeat the dose of sodium amytal intravenously, making a total of 1.5 gm in 6 hours. Within 4 hours the patient was again awake and was willing to stay in bed and take fluids and medication by mouth. He showed definite evidence of a paranoid psychosis, however, and believed that there was a plan in motion to do him bodily harm. It was impossible to reason with him on this subject, although in other matters he was moderately co-operative.

The conviction is general that action should be taken upon the basis of demonstrated need and as experience cumulates to indicate that such action is likely to attain ends in a nation comprising forty-eight states in which climatic, economic and social conditions vary greatly

this conservative setting the so-called "Principles and Proposals" were then set forth⁵⁻⁸

In the course of but seven years these principles and proposals have been generally accepted, and have already become almost ultraconservative — believe it or not — the committee was charged with revolution. Its members were accused of stabbing their fellow practitioners of American medicine in the back by releasing such radical material to the press. That the subject was the improvement of medical care and that the statement had been sent to the medical societies and medical journals of the country was generally overlooked. The fact that the editor of the *Journal of the American Medical Association*, prior to the date of release of the publication, referred to the statement as a revolt probably augmented the publicity. Amusing in retrospect is the fact that several members were severely criticized by the trustees and staffs of well known hospitals because of advocating the following:

That public funds should be available for medical research as essential for high standards of practice in both preventive and curative medicine, that public funds should be made available to hospitals that render service to the medically indigent and for laboratory and diagnostic and consultative services, and that in allocation of public funds existing private institutions should be utilized to the largest possible extent and that they may receive support so long as their service is in consonance with the above principles.

The advocacy of such proposals was felt to threaten the existence of private institutions. Well, many of these institutions are now seeking extensive financial support from the federal government, and, as remarked by Dr. Bauer, even the American Medical Association approves the allocation of public funds to private hospitals, as provided in the Hill-Burton Bill now before Congress. It is particularly amusing and informative to quote from an editorial that appeared at that time in the *Journal of the American Medical Association*.⁹

It should not be necessary to point out again in the JOURNAL the danger of federal subsidies for medical schools. The danger of putting the government in the dominant position in relation to medical research is apparent. Still more serious is the fifth proposal, to the effect that the government subsidize private hospitals. The tender of governmental funds to such institutions appeals to the unthinking physicians who have endorsed these principles and proposals. Most conspicuous on the list are the names of those deans and heads of departments in medical schools who may have signed because they saw a possibility of getting government money for clinics and dispensaries. Certainly the unthinking endorsers of the principles owe to the medical profession some prompt disclaimers.

The recent hearings on the federal financing of medical research and education before the Senate Subcommittee on Wartime Health and Education¹⁰ provide the best answer to such caustic comment. Indeed, under the leadership of essentially the same officials, the American Medical Association has

now proposed the establishment of a federal authority for medical research and education, with initial annual disbursements of \$25,000,000 for medical research and \$50,000,000 for medical education.*

PROFESSIONAL LEADERSHIP

Perhaps the American Medical Association owes the medical profession some belated disclaimers. At least there are many physicians who believe that this lack of forethought on its part has inhibited the development of wise professional opinion concerning the precautions that should be taken in such expenditure of public funds, for there are, of course, obvious dangers to be avoided. Since such lack of leadership is of serious significance to the medical profession and the public alike, should we forget the past, agree with Dr. Bauer by saying, "So what" and applaud the continuation of past policies in the present?[†] The American Medical Association still endorses the activities and emotional propaganda of the National Physicians' Committee for the Extension of Medical Service. Recent editorials in the *Journal of the American Medical Association* on the American Public Health Association's proposals for a nationwide health plan¹²⁻¹³ and on the Health Conference's "Principles of a Nation-Wide Health Program"¹⁴⁻¹⁶ still attest to a continuation of the same intolerant policy of suppressing constructive consideration of the problems confronting the medical profession. Possibly we, according to good democratic and conservative principles, should reflect on the wisdom of this leadership in order that we may intelligently vote as members of the profession to continue or discontinue it.

LIBERTY OF THOUGHT, SPEECH AND PRESS

Many physicians regret this tendency within the American Medical Association to restrict considered discussion and minority opinion, since they believe that it inhibits the development of sound progressive thought and is in no little degree responsible for the notoriously reactionary character of official medical opinion and policy. Certainly with few exceptions, such as the *New England Journal of Medicine*, the *Journal of the American Hospital Association*, *Hospitals* and the *American Journal of Public Health*, the record indicates that little opportunity is provided for the expression of minority opinion through the journals and other channels of so-called "organized medicine."[‡] Moreover, minority opinion within these medical societies is frequently buried by the practice of expressing the majority opinion as a unanimous one. A book en-

*Recently the editor of the *Journal of the American Medical Association* appeared before a Senate committee and advocated the establishment of a national science foundation which would finance medical research and medical education.

‡The *Journal of Pediatrics* has recently published interesting discussions in a section entitled "The Social Aspects of Medicine."

SYMPOSIUM ON MEDICAL SOCIOLOGY

MINORITY VIEWS ON IMPROVING MEDICAL CARE*

ALLAN M BUTLER, M D †

LAST week Dr Bauer,¹ a trustee of the American Medical Association, spoke to you on that organization's view concerning the problems of medical care. The subject assigned me concerns views that differ from those of the American Medical Association. Strangely enough, in this democratic country, whose people believe in the free expression of minority opinion, the propriety of presenting such views on medical matters is questioned by some physicians. Hence, their mere consideration here will almost inevitably be subject to criticism. A politician would probably have declined the assignment. Indeed, an officer of the American Medical Association even refused an invitation to present to you the opinions of that body.²

To allay immediately either your fear or your expectation of radical opinion, let me assure you that I know of no one who does not heartily concur with the opinion expressed by Dr Bauer last week—namely, that extension or change of our medical services should be accomplished by evolutionary processes. No opinions expressed here, therefore, will be contrary to that sound conservative dictum. I trust, however, that we agree, that evolution connotes reaction manifested by a series of changes. From the standpoint of sociology, one may ask whether it is failure to react or reaction to changing circumstance that results in revolution rather than evolution. Was it, for example, reactionary monarchy or liberal philosophy that precipitated revolution in the evolution of representative government?

EVOLUTION, NOT REVOLUTION

In considering a nationwide health program, it is pertinent to remember that, as stated by Terris,³ compulsory health insurance, which is often considered to be an entirely new and unprecedented method of financing medical care in the United States, was used in this country as early as 1798. Much can be learned from study of the results of the act of Congress of that year, "for relief of sick or disabled seamen," which began by applying the method of monthly payroll deduction. Under this act grew the Marine hospitals. In 1884, Congress substituted a tonnage tax for the payroll-deduction method of financing the service, because the latter

put American shipping in an unfavorable competitive position. Perhaps there is food for thought here concerning the financing of individual state sickness-insurance plans by payroll deductions.

Over a course of years, the Marine Hospital Service evolved into the United States Public Health Service, which, as you know, is supported by general tax funds, and which, it may be pertinent to remark, maintains high administrative and scientific standards as well as freedom from political influence. The same high standards and freedom from political patronage or corruption pertain to the use of federal funds under the federal programs for crippled children and maternal and child health and for the Emergency Maternal and Infant-Care Program. With such evidence before us, need we accept the statement that funds expended under a nationwide health program must inevitably fall prey to the spoils system? A recent article in the *New England Journal of Medicine* by Wendell Berge,⁴ Assistant Attorney General of the United States, provides reassuring comment pertinent to this question and to other aspects of medical sociology.

With all the experience of this and other countries with government sickness insurance and tax supported medicine, characterization of such medical-care programs as revolutionary reflects either historical ignorance or lack of awareness of current trends.

In 1937, as a contribution to the discussion of the subject of medical care in the United States, the Committee of Physicians for the Improvement of Medical Care formulated certain principles and proposals suggesting lines along which effort might be made by voluntary, local, state and federal agencies to improve medical care.⁵⁻⁷ The introductory statement included the following:

It is recognized that the medical profession is only one of several groups to which "medical care" is of vital concern. Close co-operation between physicians, economists and sociologists is essential. Nevertheless the medical profession should initiate any proposed changes because physicians are the experts upon whom communities must depend. Unless the medical profession is ready to co-operate with these other groups they cannot expect to play successfully the part which they should play nor can they expect to enlist the sympathetic understanding of legislative bodies.

It seems to us probable that certain alterations in our present system of preventing illness and providing medical care may become necessary, indeed, certain changes have already occurred. Medical knowledge is increasing rapidly and is becoming more complex. Changes in economic and social conditions are taking place at home and abroad. Medicine must be mobile and not static if medical men are to act as the expert advisers of those who convert public opinion into action.

*This is the eighth of a series of nine lectures on medical sociology given weekly at Harvard Medical School during January, February and March 1945. They were sponsored by the Department of Preventive Medicine and were primarily intended for third year students. These articles will temporarily replace the reports "Medical Progress."

†Chief, Children's Medical Service, Massachusetts General Hospital; associate professor of pediatrics, Harvard Medical School.

que. That they should cherish the independence, freedom and artistic quality of their individual endeavor is natural and, in so far as it does not too greatly limit the quality and efficiency of their work, desirable. But the increase in medical knowledge, in the facilities necessary for its adequate application and in the cost of medical care render the average practitioner's position increasingly difficult and vulnerable. As so well outlined

Dr Dean Clark²³ in the second lecture of this series, the practitioner's income is meagre, his task and responsibilities immense, his independence more imaginary than real, and his future uncertain. He is therefore worried by, sometimes alarmed by and occasionally resentful of the change in the structure of medical practice that is slowly but surely occurring. His elected representatives, who are either salaried officials or elderly physicians successful under the present system, are usually the most ardent advocates of fee-for-service practice and bitterly defend its existence.

A hundred years ago the guilds in trying to protect their artisan interests resisted the integration of industry. Yet for better or for worse, integrated mechanized industry grew, the artisan was displaced, unemployment appeared, and wages fell. The industrial revolution came. Perhaps it is pertinent to ask. Can the American Medical Association in playing the guild role defend the physician artisan of today? Many think it a losing game. To find the American Medical Association on the defensive, as evidenced by Dr Bauer's lecture last week, and fighting only a delaying action against the progressive integration and prepayment of medical care is not so unexpected. It may, however, be puzzling to the young physician who has learned the medicine practiced by highly integrated group services, who aspires to contribute effectively to a high quality of medical service and to participate in the development and application of new knowledge and who has no vested interest in what may, not too inappropriately, be called the *status quo ante bellum*.

It is particularly pertinent that the young physician should consider the pattern of medical practice that will best serve society by quality and amount of service and thus better the public's respect for and financial support of the profession that will be his in the future. Will his experience with the inevitably defective emergency medical services of the armed forces make him an advocate of individualistic fee-for-service practice? Or will he, discounting the handicaps imposed by the emergency nature of these services, be impressed with the possibilities of well integrated group salaried practice? The considerations of a group of British physicians, as given in the *Medical Planning Research Interim General Report*,²⁴ set forth interesting opinion. The recent British White Paper provides more evidence concerning British trends. How irrelevant to current problems is the manner in

which representatives of the American Medical Association harp on the past defects of the English system, when those defects have been so generally recognized and are being corrected, and when no one is advocating the adoption of that system! Parenthetically, it may be remarked, that if the American Medical Association were correcting its past policies as constructively as are the British, mention of them would be irrelevant. Important questions about the English system are: Is it being discarded or extended? Do the doctors advocate its discontinuance? On the basis of past experience, how are they now proposing to extend government insurance? Instead of discussing these pertinent questions, spokesmen of the American Medical Association continue to comment on the English system of government sickness insurance in the manner that the Michigan State Medical Society²⁵ in 1934 declared was misrepresentation of fact and that representatives of the British medical profession have frequently described as inaccurate. Referring to comments made by the Bureau of Medical Economics of the American Medical Association, the secretary of the British Medical Association writes "Almost every page of the pamphlet provides matter for criticism on the score of inaccuracy or unfair presentation. [It] does not appear a very reliable account of the British Health Insurance system."²⁶ Another indictment of this bureau comes from an article by E. L. Brown,²⁷ research associate of the Russell Sage Foundation. "The potentially important Bureau of Economics," he writes, "which publishes statistics and studies of the distribution of physicians and forms of medical practice, is not only ultraconservative in philosophy, but the facts it presents are often incorrect or interpreted with bias, and even its statistical work is undistinguished."

The slogans and phrases resorted to by American Medical Association spokesmen are felt by many to favor an emotional rather than tolerant consideration and too frequently to constitute a misinterpretation that inhibits constructive thought. "It now becomes necessary," according to Dr Sensenich,²⁸ a trustee of the American Medical Association, "to protect the public by opposing the substitution of an unAmerican system of medicine with bureaucratic regimentation of patients and physicians, such as would destroy those American qualities of medical service that are most important to health and the American way of life." The National Physicians' Committee, which is supported in part by donations from pharmaceutical houses and whose activities have been endorsed by the House of Delegates of the American Medical Association, spends \$250,000 a year on such emotional propaganda, distributing dramatic pamphlets throughout the country through the agency of drugstores. Even a trustee of this committee, Dr Leland S. McKittick,²⁹ characterizes its attack on the

titled *The Political Life of the American Medical Association*,¹⁷ which should be read by all physicians, explains the manner of accomplishing this without openly transgressing the democratic principles of the Association. Is it or is it not odd that doctors, who are so generally individualists in character and practice, acquiesce in regimentation and suppression of minority opinion within their professional societies? Although most doctors are probably advocates of states' rights, they acquiesce in the American Medical Association's attempts to prevent state and other medical societies from expressing opinions different from its own.

For example, in June, 1934, the Board of Regents of the American College of Surgeons promulgated a prepayment plan for medical care at approved hospitals to members of the staffs of such hospitals and to physicians acceptable to such staffs. Immediately after this, the Judicial Council of the American Medical Association presented the following report,¹⁸ which was unanimously adopted by the House of Delegates:

WHEREAS, the American Medical Association, including 100,000 physicians, is the only democratic body representing the organized profession of this country through delegates regularly elected through county and state medical societies, and

WHEREAS, other medical organizations and groups, representing selected groups of specialists, have from time to time issued pronouncements of policies in the field of medical economics and medical practice which do not represent the views of organized medicine and which purport to guide the medical profession and the public in the administration of medical affairs, and

WHEREAS, the House of Delegates of the American Medical Association has repeatedly condemned the issuing of such announcements and policies, and

WHEREAS, the Board of Regents of the American College of Surgeons, assembled in Chicago on Sunday, June 10, promulgated a policy including a prepayment plan for medical care restricted to so-called "approved hospitals," to members of the staffs of such hospitals and to physicians acceptable to such staffs, and

WHEREAS, this action of the Board of Regents of the American College of Surgeons has been spread to the people of the United States through the public press on the opening day of the annual session of this House of Delegates, therefore be it

RESOLVED, That the House of Delegates request the Board of Trustees of the American Medical Association and Judicial Council to ask the Board of Regents of the American College of Surgeons, who are themselves members of the American Medical Association, to explain the reasons for their action and to justify the attempt by this small group within a specialistic organization to legislate for all the medical profession of this country, truly represented only by the American Medical Association.

Concerning the editorial in the *Journal of the American Medical Association* supporting this resolution, Dr J H Means¹⁹ in a letter to the editor commented:

Your editorial entitled "Organized Medicine and Medical Care," July 14, 1934, is a truly amazing utterance. By it we learn that members of what you are pleased to call organized medicine are entitled to express no opinions on the great problem of medical service to the community, either as individuals or as minority groups, which differ from the official opinions of the House of Delegates of the American Medical Association. To say that [minority] groups are morally obligated to remain silent,

when their honest convictions run contrary to official doctrine, is hardly appropriate in a democracy like whose founders sought particularly to safeguard minority rights and opinions. I would like to quote from an editorial in the July 6 issue of the *Harvard Alumni Bulletin*: "Those who call for the preservation of American 'Institutions' do not always remember that among the most venerable and cherished of these institutions is liberty of thought and speech and press, and that nothing in America could be more 'radical' than its suppression."

The Board of Trustees of the American Medical Association replied, "It does not seem desirable to publish your communication addressed to the *Journal*."²⁰

As stated in a paper read before the United States Chamber of Commerce,^{20, 21} an extreme example of an attempt to suppress discussion and inhibit activities by physicians is furnished by the proposal in 1938 of the Council of the Medical Society of the State of New York to amend the bylaws as follows: "The component county medical societies, their officers, committeemen and members shall not initiate any policy, propose any legislation or participate in any activities that are contrary to the policies of the Medical Society of the State of New York." Fortunately, this was so objectionable to many members that the amendment was not accepted. Dr Bauer has taken exception to this reference because the proposal was overwhelmingly rejected at the meeting of the Council. I wonder, however, if he would not concede that discussion of the proposal prior to the meeting was significant. The recent publications of the Association of American Physicians and Surgeons and that association's advocacy of professional excommunication of physicians who do not subscribe to its policies attest to the fact that proposals of this nature do not altogether lack professional endorsement.

This matter of suppressing discussion within the profession is mentioned and briefly documented here not in the spirit of hostility, but rather to present the opinion of those who plead for a liberalism within the medical profession that will permit expression of minority opinions and thus tolerate consideration, reasoned debate and constructive criticism. Only by such democratic processes will the complicated problems of providing better medical care effectively be solved. Only by free discussion of current problems will evolution be orderly and revolution be avoided.

THE GUILD NATURE OF THE AMERICAN MEDICAL ASSOCIATION

That the American Medical Association should defend the present individualistic fee-for-service type of medical service is not surprising, as remarked by Dr Franz Goldmann in the discussion following his lecture²² of several weeks ago. The great majority of its members are practicing and earning their living by that type of practice. These practitioners in some respects enjoy an independence that in our highly organized modern society is almost

h on the American Medical Association's attitude. If the medical profession would approach the problem with good will and eagerness for improvement, much could be accomplished. If, on the other hand, spokesmen of your profession belittle the need for improvement and display intolerance toward discussion, the evolution of beneficial change is inhibited. "A major obstacle," says a recent reviewer in *Fortune*,³⁷ "has been organized United States medicine, as represented by the century-old American Medical Association."

In a unanimous ruling concerning the suit brought by the Department of Justice against the American Medical Association and the District of Columbia Medical Society for restraint of trade, the Court of Appeals of the District of Columbia, through Justice Miller, made the following statement³⁸

Professions exist because the people believe they will be better served by licensing especially prepared experts to minister to their needs. The licensed monopolies which professions enjoy constitute in themselves, severe restraints upon competition. But they are restraints which depend upon capacity and training, not special privilege.

Neither do they justify concerted criminal action to prevent the people from developing new methods of serving their needs. There is sufficient historical evidence of professional inadequacy to justify occasional popular protests.

The better educated laity of today questions the adequacy of present-day medicine. Their challenge finds support from substantial portions of the medical profession itself. The people give the privilege of professional monopoly and the people may take it away.

The provision of a leadership that will defend the prestige and privilege of your profession by recognizing changing circumstance and directing constructive action depends in no small degree on you, young physicians.

INCREASING COSTS

As medicine has become more effective and the ultimate burden of illness to society has diminished, the cash costs of medical care have increased. As society has become more industrialized and individuals have become more dependent on wages, illness has with increasing frequency been associated not only with increasing costs but also with loss of wages and has therefore entailed greater financial stress. Thus, the inability of the sick to meet the costs of illness has increased. Families with incomes of \$3000 a year are reported by the American Medical Association to be unable to meet the costs of serious illness. Hospitals in large cities admit persons as charity patients whose family income is \$2500 a year. Physicians therefore today provide free service to many persons whose incomes are more than double the income of the average resident of the United States. Viewed from another aspect, our hospitals for chronic disease are used by persons whose productive abilities before affliction represented a cross-section sample of the community. Chronic illness in depriving them of their earning capacity, and subjecting them to the expenses of modern medical care has rendered rich and poor

alike unable to meet the continued costs of such illness. You or I, regardless of our present earning capacity, may, except by the grace of God, be the chronic invalid of tomorrow who will be a charity patient in a public institution. Thus, the charity tradition in medicine has extended far beyond its original concept. It now approximates a billion-dollar business that concerns a large portion of society. One may well ask: How fairly is the burden of this charity business dispersed? How adequately is it financed? How efficiently is it operated?

Although there is no doubt about the medical profession's carrying a great share of the burden, the degree to which this burden is distributed among doctors and the indirect recompense they receive for charity work is seldom considered in a business-like manner. The physician charges his private patients an arbitrary amount, according to a rough estimate of ability to pay, which will be adequate to compensate for the service rendered those who cannot or do not pay. This custom both accepts as satisfactory the meager information on which the arbitrary professional fees are based and ignores the totally inadequate means of distributing the amounts so collected among physicians according to the actual charity services rendered. Not infrequently the physician whose fees are highest contributes the least charity service. Too frequently the doctor whose patients can pay but small fees serves many without remuneration. Custom also results in the physician's giving medical care to the hospital's charity patients without remuneration in return for the prestige and experience so gained and for the privilege of utilizing hospital facilities for the care of his private patients. For the latter, however, the physician is hardly beholden to the hospital, because the latter, if reasonably well managed, makes a profit on the private patients whom the doctor provides. What happens to the hospital if the doctor provides no patient?

Thus, in these and possibly other respects the rationale of the current system of indirect professional remuneration for charity service is not too clear. But whatever the rationale, the amount of such service rendered by the profession attests not only to an awareness of its public-service role but also to its long-standing recognition of the inability of many persons to meet the costs of illness.

Great as these charity services and high as the standards are, they are but a fraction of what they might be. Indeed, there are those who believe that the unique persistence of the charity tradition is one of the principal impediments to a better quality of medicine. What is the evidence?

It has already been intimated that the charity tradition is the principal cause of the arbitrary character of professional charges. Can it be said with fairness that it has been intimately related to present inadequate financing of professional and hospital service alike and underpayment of labora-

Wagner-Murray-Dingell bill as "violent [and] somewhat undignified" The old bogie of a so-called "third party" coming between doctor and patient is again given a leading role This cry concerning the evils of a third party and this charge that any modification of individualistic private practice will limit the "free choice of physician" have been used so loosely and misleadingly in regard to almost any well organized group health plan as to suggest either dishonesty or lack of intelligence This propaganda does not mention that the excellent medical care provided by the Mayo Clinic, the Lahey Clinic, the Baker Memorial Unit of the Massachusetts General Hospital and all the larger university teaching hospitals throughout the country includes not the evil but the benefit of a third party The propaganda does not mention that a majority of the American people have little free choice of physician in any significant sense And such propaganda concerning the Wagner-Murray-Dingell National Health Bill²⁹ does not mention the fact that under this plan millions of people would be provided for the first time with the opportunity of choosing a family physician and that thus the American public would experience a greater free choice of physician than pertains today

At a time when a recent survey made by the National Opinion Research Center of the University of Denver indicates that 68 per cent of representatively sampled Americans favor an extension of the Social Security Law to cover payments for doctor and hospital care, the distribution of distorted and hysterical propaganda may satisfy elderly physicians whose concern is to hang on to the *status quo* for a few years, but hardly contributes a sound solution to the public demand and your professional future Are not your and the public's interests more effectively served by the careful analyses and constructive criticisms set forth in statements by the Committee of Physicians for the Improvement of Medical Care, Incorporated,³⁰ and by the Physicians' Forum,³¹ and in the pamphlet covering the Health Program Conference?¹⁵

ADEQUACY OF MEDICAL CARE

Why is the American Medical Association so touchy about the adequacy of medical care? To state, as Dr Bauer and its representatives so often do,^{1, 27} that medical care in the United States is better than in any European country having compulsory sickness insurance is irrelevant and misleading It implies that compulsory sickness insurance rather than the economic and social disorders incident to the bellicose state of Europe during the last thirty years is the limiting factor in the advance of European medicine The proper test of the adequacy of our medical care, as stated by Dr I S Falk,³² "is not that health is better today than it was a decade or a generation or a century ago or than in some other country, nor that medicine

and public health accomplish more now than it did then By such comparisons, health programs were good in 1900 and perhaps even in 1850 A valid test is whether we do well and effectively about what we know how to do and can do By this test there is no ground for complacency"

The American Academy of Pediatrics at its annual meeting in November, 1944, unanimously stated that "a large number of children do not receive preventive and curative care compatible with present day standards of good pediatric care."³³

The Maternal Mortality Committee of the Committee on Maternal Health of the Minnesota State Medical Association³⁴ makes the following comments in the summary of its report

1 From July 1, 1941, through June 30, 1942, a review was made of the maternal mortality in the State of Minnesota

2 The absence of any consultation in 56 per cent of the cases, the presence of less than 10 per cent adequate consultation, and the inadequacy of two thirds of the consultations which were obtained raises certain obvious questions

3 With a liberal interpretation, 43 patients (84 per cent) were well when first seen and died later

4 One half of the inadequate consultations in our series were supplied by specialists, men who by training and experience should be capable of furnishing superior consultative services

5 There was an unfortunately high incidence of operative deliveries (56.2 per cent), some of the deaths resulting directly from the operative procedure

6 Seventy-seven (82 per cent) had no pelvic measurement or less than the minimal requirements for adequate prenatal care laid down by the Committee for the Minnesota Maternal Study

7 The great majority of physicians' office records were of very little value as regards accurate information, if indeed there were any records

8 According to the minimum requirements for adequate obstetrical care as adopted by this committee, adequate care was given in only 1.8 per cent in the prenatal period, 6.3 per cent in labor and for delivery and 3.6 per cent in the post-partum period

9 A blood Wassermann has long been considered an absolute essential — yet 73.2 per cent of these cases did not have venepuncture for a Wassermann test at the first prenatal visit, and 62.5 per cent had no Wassermann test in association with the pregnancy

10 The Committee agreed that 82 deaths (73 per cent) were preventable and that in all but 4 cases the physician was wholly or partially responsible

Under the Michigan Community Health Project an attempt has been made for several years to encourage physicians to immunize children by assuring each physician remuneration for such procedures In the area covered, the approximate percentages of children immunized against diphtheria up to 1944 were as follows under one year, 10 per cent, under two years, 25 per cent, and under five years, 37 per cent The corresponding figures for immunization against smallpox were 4 per cent and 34 per cent³⁵

The Interim Report on Wartime Health and Education from the Senate Committee, popularly known as the Pepper Committee, presents findings and recommendations that deserve consideration Many physicians believe that the first step to improving medical care is a frank admission of responsibility for improvement This is why I have dwelt at length

h on the American Medical Association's atti-

If the medical profession would approach the
lem with good will and eagerness for improve-
t, much could be accomplished. If, on the other

INCREASING COSTS

As medicine has become more effective and the
limate burden of illness to society has diminished,
he cash costs of medical care have increased. As
ociety has become more industrialized and in-
dividuals have become more dependent on wages,
Illness has with increasing frequency been asso-
ciated not only with increasing costs but also with
oss of wages and has therefore entailed greater
inancial stress. Thus, the inability of the sick to
neet the costs of illness has increased. Families
with incomes of \$3000 a year are reported by the
American Medical Association to be unable to meet
the costs of serious illness. Hospitals in large cities
admit persons as charity patients whose family
income is \$2500 a year. Physicians therefore today
provide free service to many persons whose incomes
are more than double the income of the average
resident of the United States. Viewed from another
aspect, our hospitals for chronic disease are used by
persons whose productive abilities before affliction
represented a cross-section sample of the community.
Chronic illness in depriving them of their earning
capacity, and subjecting them to the expenses of
modern medic care has rendered rich and poor

alike unable to meet the continued costs of such
illness. You or I, regardless of our present earning
capacity, may, except by the grace of God, be the
chronic invalid of tomorrow who will be a charity
patient in a public institution. Thus, the charity
tradition in medicine has extended far beyond its
original concept. It now approximates a billion-
dollar business that concerns a large portion of
society. One may well ask: How fairly is the burden
of this charity business dispersed? How adequately
is it financed? How efficiently is it operated?

Although there is no doubt about the medical
profession's carrying a great share of the burden,
the degree to which this burden is distributed among
doctors and the indirect recompense they receive
for charity work is seldom considered in a business-
like manner. The physician charges his private
patients an arbitrary amount, according to a rough
estimate of ability to pay, which will be adequate
to compensate for the service rendered those who
cannot or do not pay. This custom both accepts
as satisfactory the meager information on which
the arbitrary professional fees are based and ignores
the totally inadequate means of distributing the
amounts so collected among physicians according to
the actual charity services rendered. Not infre-
quently the physician whose fees are highest con-
tributes the least charity service. Too frequently
the doctor whose patients can pay but small fees
serves many without remuneration. Custom also
results in the physician's giving medical care to the
hospital's charity patients without remuneration
in return for the prestige and experience so gained
and for the privilege of utilizing hospital facilities
for the care of his private patients. For the latter,
however, the physician is hardly beholden to the
hospital, because the latter, if reasonably well
managed, makes a profit on the private patients
whom the doctor provides. What happens to the
hospital if the doctor provides no patient?

Thus, in these and possibly other respects the
rationale of the current system of indirect pro-
fessional remuneration for charity service is not too
clear. But whatever the rationale, the amount of
such service rendered by the profession attests not
only to an awareness of its public-service role but
also to its long-standing recognition of the inability
of many persons to meet the costs of illness.

Great as these charity services and high as the
standards are, they are but a fraction of what they
might be. Indeed, there are those who believe that
the unique persistence of the charity tradition is
one of the principal impediments to a better quality
of medicine. What is the evidence?

It has already been intimated that the charity
tradition is the principal cause of the arbitrary
character of professional charges. Can it be said
with fairness that it has been intimately related to
present inadequate financing of professional and
hospital service alike and underpayment of labora-

Wagner-Murray-Dingell bill as "violent [and] somewhat undignified." The old bogie of a so-called "third party" coming between doctor and patient is again given a leading role. This cry concerning the evils of a third party and this charge that any modification of individualistic private practice will limit the "free choice of physician" have been used so loosely and misleadingly in regard to almost any well organized group health plan as to suggest either dishonesty or lack of intelligence. This propaganda does not mention that the excellent medical care provided by the Mayo Clinic, the Lahey Clinic, the Baker Memorial Unit of the Massachusetts General Hospital and all the larger university teaching hospitals throughout the country includes not the evil but the benefit of a third party. The propaganda does not mention that a majority of the American people have little free choice of physician in any significant sense. And such propaganda concerning the Wagner-Murray-Dingell National Health Bill²⁹ does not mention the fact that under this plan millions of people would be provided for the first time with the opportunity of choosing a family physician and that thus the American public would experience a greater free choice of physician than pertains today.

At a time when a recent survey made by the National Opinion Research Center of the University of Denver indicates that 68 per cent of representatively sampled Americans favor an extension of the Social Security Law to cover payments for doctor and hospital care, the distribution of distorted and hysterical propaganda may satisfy elderly physicians whose concern is to hang on to the *status quo* for a few years, but hardly contributes a sound solution to the public demand and your professional future. Are not your and the public's interests more effectively served by the careful analyses and constructive criticisms set forth in statements by the Committee of Physicians for the Improvement of Medical Care, Incorporated,³⁰ and by the Physicians' Forum,³¹ and in the pamphlet covering the Health Program Conference?¹⁵

ADEQUACY OF MEDICAL CARE

Why is the American Medical Association so touchy about the adequacy of medical care? To state, as Dr. Bauer and its representatives so often do,³² that medical care in the United States is better than in any European country having compulsory sickness insurance is irrelevant and misleading. It implies that compulsory sickness insurance rather than the economic and social disorders incident to the bellicose state of Europe during the last thirty years is the limiting factor in the advance of European medicine. The proper test of the adequacy of our medical care, as stated by Dr. I. S. Falk,³² "is not that health is better today than it was a decade or a generation or a century ago or than in some other country, nor that medicine

and public health accomplish more now than it did then. By such comparisons, health provisions were good in 1900 and perhaps even in 1850. The valid test is whether we do well and effectively, and what we know how to do and can do. By this test there is no ground for complacency."

The American Academy of Pediatrics at its annual meeting in November, 1944, unanimously agreed that "a large number of children do not receive preventive and curative care compatible with present day standards of good pediatric care."³³

The Maternal Mortality Committee of the Committee on Maternal Health of the Minnesota State Medical Association³⁴ makes the following statements in the summary of its report:

1 From July 1, 1941, through June 30, 1942 a total of 1,000 cases of maternal mortality in the State of Minnesota was made of the maternal mortality in the State of Minnesota.

2 The absence of any consultation in 56 per cent of the cases, the presence of less than 10 per cent adequate consultation, and the inadequacy of two thirds of the consultations which were obtained raises certain obvious questions.

3 With a liberal interpretation, 43 patients (38.4 per cent) were well when first seen and died later.

4 One half of the inadequate consultations in our series were supplied by specialists, men who by training and experience should be capable of furnishing superior coordinated care.

5 There was an unfortunately high incidence of operative deliveries (56.2 per cent), some of the deaths resulted directly from the operative procedure.

6 Seventy-seven (82 per cent) had no pelvic measurement or less than the minimal requirements for adequate prenatal care laid down by the Committee for the Minnesota Maternal Study.

7 The great majority of physicians' office records were of very little value as regards accurate information, indeed there were very few records.

8 According to the minimum requirements for adequate obstetrical care as adopted by this committee, adequate care was given in only 1.8 per cent in the prenatal period, 6.3 per cent in labor and for delivery and 3.6 per cent in the post-partum period.

9 A blood Wassermann has long been considered an absolute essential — yet 73.2 per cent of these cases did not have venepuncture for a Wassermann test at the first prenatal visit, and 62.5 per cent had no Wassermann test in association with the pregnancy.

10 The Committee agreed that 82 deaths (73 per cent) were preventable and that in all but 4 cases the physician was wholly or partially responsible.

Under the Michigan Community Health Project, an attempt has been made for several years to encourage physicians to immunize children by assuring each physician remuneration for such procedures. In the area covered, the approximate percentages of children immunized against diphtheria up to 1944 were as follows: under one year, 10 per cent, under two years, 25 per cent, and under five years, 37 per cent. The corresponding figures for immunization against smallpox were 4, 16 and 34 per cent.³⁵

The Interim Report on Wartime Health and Education from the Senate Committee, popularly known as the Pepper Committee, presents findings and recommendations that deserve consideration.

Many physicians believe that the first step to improving medical care is a frank admission of room for improvement. This is why I have dwelt at such

eneration of the young physician and the value his contribution to society appears not only to be unique but also to be dependent on the unique charity tradition of his profession

Proud as we may be of the generosity and idealism instilled by this tradition in the past, one should permit sentiment to obscure the incompatibilities between it and reality in the present. Much evidence indicates that the charity tradition not only imposes too heavy a burden on the profession but also provides a quality of medicine well below that which could readily be provided. The disruption of medical services by the war, the inevitable relocation of many medical veterans and the current discussion of a national health program make consideration of possible revisions of economic aspects of our system of medical care particularly opportune.

REDUCING THE BURDEN BY INSURANCE

At long last the public and the medical profession have come to realize that those who are unfortunate enough to suffer illness cannot be expected to pay the costs of modern medical care at the time when illness has decreased their income and increased their expenses. They appreciate that the liability is too extensive to be assigned to charity. They also see that post-payment bank-loan schemes of meeting the costs of illness merely provide more time to pay the costs that have fallen heavily on the unfortunate sick, whereas insurance or tax-supported services spread the costs to include those who have not suffered the financial burden of illness. Thus, schemes involving the latter methods of paying medical costs are being generally advocated. If wisely devised, there is little doubt that they will result in the more adequate financing of medical care. If they are unwisely devised, there will be little improvement in the financial support of better medicine and a wasteful expenditure of public funds on poor medical care.

The Committee on the Costs of Medical Care not only recognized this in 1930 but also recognized the important implication as regards the pattern of medical practice.³⁸ This committee, as you know, recommended that the budgeted medical service for home, office and hospital care be furnished largely by integrated professional groups, preferably organized around hospitals.

Representatives of the American Medical Association and of the state medical societies have belatedly admitted that application of the insurance cost-sharing principle to medical costs is per se neither economically unsound nor detrimental to the quality of medical care. But this admission merely introduces the problem. It neither contributes to the solution nor indicates the implication regarding the structure of medical practice that the Committee on the Costs of Medical Care recognized. Among the factors that deserve careful considera-

tion in any scheme is the establishment of proper administrative supervision and the development of well integrated units for providing medical care.

The Problem of Administrative Supervision

The payment of the costs of medical care by a third party — whether the government or a private agency — necessitates an administrative supervision of the cost and quality of the care provided that is not required when the cost is paid for by the recipient. When the transaction is between doctor and patient, there is a check on the amount of service requested and rendered, but when a third party pays for the service, there is no such check. The wide experience of commercial insurance schemes shows that 85 per cent of patients and doctors play fair, but that some 15 per cent run up costs that embarrass the schemes financially. Hence a mechanism for supervising the quality and quantity of care rendered is desirable. This, of course, cannot be provided without to some extent infringing on the almost complete independence that the individual practitioner thinks he enjoys today. The desire to maintain this pseudoindependence and to avoid being subjected to supervision is the main reason why the medical profession has opposed insurance medicine so long. Many physicians and medical associations, in a manner reminiscent of the old guilds, are defending this independence of the solo practitioner. Thus, as insurance medicine becomes inevitable, they are advocating forms of insurance medicine that are devoid of supervision.

Their first choice in defending this guild interest of practitioners is that payments under any government insurance scheme be made as cash benefits to patients, not as payments to doctors for service. This places a certain amount of money in the hands of the patient and leaves the doctor free to charge what he wishes. Obviously it is little more than a public dole under the pretext of being medical care. It makes no provision for economy in the expenditure of public funds nor does it reflect any concern for the quality of care purchased. Since this method of payment is usually recommended for governmental schemes and has rarely been advocated for any of the several schemes operated under the aegis of medical societies, the impracticability of such cash benefits is apparently fully appreciated but merely ignored in connection with government-insurance medicine.

The second choice of these defenders of the independence of physicians is that doctors be paid on a fee-for-service schedule by the insurance agency and be free to charge an additional fee to the patient. Under this scheme, for example, a doctor might be paid \$150 by the insurance agency for an appendectomy. The doctor then charges the patient an additional \$100, which nets him perhaps \$50 more than his regular private fee of \$200. Such a scheme ignores the equitableness of the total cost

tory and other hospital personnel? Or is it a primary factor in the lack of integration of hospital medical care and of student training?

With the exception of a few major teaching hospitals or private clinics, the service of doctors to hospital-ward patients lacks continuity. In the average hospital, the practitioners of the community care for the charity patients on a monthly rotation basis. One visiting physician may do the diagnostic workup of a case and start a well planned therapeutic regime that is disregarded or discarded by his successor. Or even if the planned therapy is continued, the doctor rarely has an opportunity to follow the therapeutic result intimately enough to provide maximal benefit to himself or his patient. Even if the patient returns to the outpatient department for follow-up, the chances are that he will be seen by a doctor other than the one who cared for him as a ward patient.

In the large teaching hospitals, the salaried staff may provide more continuity for ward care. But here also there is a lack of integration between outpatient and ward care. And here, too, the continued rotation or promotion of interns and residents through the various divisions of the hospital limits the continuity of the care they render.

Because physicians in the outpatient department provide their services on a voluntary basis for one to two and a half hours once or twice a week, continuity of service for the patient that needs care more than once or twice a week is almost impossible. If the examining physician wishes a consultation, he frequently cannot see the patient with the consultant because the consultant holds his outpatient clinic on another day. Thus, to no little degree, the charity aspect of hospital care limits the quality of such service, even though this may be good as compared to the average obtained from the private practitioner. Moreover, because it is an important factor in restricting hospital medical care to the ward and outpatient department, it limits the extent of the service rendered by integrated professional personnel and hospital facilities.

Quite rightly the physician feels that he is contributing enough charity service at the hospital. He therefore resents the extension of hospital service to the home lest it lead to one of two consequences, equally undesirable for him: that he be asked to see the patient at home who cannot afford to pay, or that the hospital through its resident staff provide home care to the patient who might otherwise pay a physician. Could there not be as clear a distinction between the paying and nonpaying patient at home as in the hospital? Resolution of the ambiguity would permit an extension of hospital services to include home care of the nonpaying patient. It would relieve the practicing doctor of the burden of home care of the nonpaying patient without infringing on his paying practice.

Such an extension would favor economy by lessen-

ing unnecessary hospitalization. For provision of home care by the hospital service would prevent not only unnecessary entry to hospitals but also undesirable prolongation of hospitalization. Second, it would improve medical education. The medical student during his four years and the intern and resident during an additional two to four years of hospital training rarely come in contact with a patient in his normal environment. Their basic patterns of medical thought about sick patients develop in the environment of hospital beds, operating rooms, laboratories and crowded outpatient clinics. Under these circumstances, it is difficult for the young physician to appreciate the particular stresses and strains in the daily life of his patient—economic burdens, family conflicts and mentally retarded children. He therefore forgets and forms the habit of belittling the effect of the patient's illness on his life and of his environment on his illness. Thus, the students' teaching tends to be limited to a therapy prescribed by medical science under the conditions pertaining in the hospital environment. These same limitations as regards personal and social implications apply equally to nursing education.

No wonder there is a demand for teaching psychosomatic medicine and more personal nursing care. But such emphasis will accomplish little. Students and teachers must be brought in contact with the patient's natural environment. The information it provides and its bearing on the health of the patient and the benefit of therapy should be utilized and appraised as thoroughly as are the data provided by the hospital laboratories. The solution of this problem of medical education is the extension of medical care from the hospital ward and outpatient service to the patient in his home.

The cost of medical education is also to some extent related to the charity tradition. As already mentioned, after his high-school education, three or four years of college and four years of medical school, the young doctor spends two to four years practicing his profession in a hospital. During this period he contributes from twelve to eighteen hours a day of service to his patients. On the assumption that the experience he thus obtains has a value that approximates that of the service he renders, he receives little or nothing the first two hospital years, perhaps \$500 the third year and possibly \$1000 a year for the fourth year. The students who can finance these many unremunerative years of medical education are not necessarily the best students or doctors. The system that provides such meager recompense therefore limits the selection of doctors. This undesirable limitation could be lessened if house-officer physicians were paid according to the value of the services they render. Surely the acquisition of valuable knowledge and experience in the early years of practice is not confined to the medical profession, yet the discrepancy between

self assure improvement in the financing of medical care

To some persons such a development of group service by hospitals and their staffs as indicated here may appear utopian. Let it be appreciated, however, that failure to provide for the development and utilization of such services under any extensive insurance scheme may destroy the very medical units from which the past improvement in medical care has emanated and on which future progress depends. Such being the case, it appears to be of concern to those interested in better medical care — doctors and laymen alike — to see that provision for the utilization and development of such services is included in any state or national health plan.

An orderly plan of financing and operating an efficient system of providing medical care should neither be damned as impractical nor hailed as the millennium. The resources made available by the one and the quality of care attained by the other will depend on a manifestation of the qualities that have brought medicine to its present high level. Lessening the occasion for charity and the limitations incident to it should provide a wider, not a narrower, field for the idealism that has under unfavorable circumstances sustained charity medicine in the past.

* * *

Such are some of the views on improving medical care that it seemed should be included in the portion of this symposium assigned to me. Some, which clearly were minority views but yesterday, are becoming majority views today. What they will be tomorrow is of obvious concern to you and, indeed, may depend on what you think about them.

to society and hardly distributes the cost of medical care satisfactorily. Moreover, it provides but little check on quality of care, other than that of gross abuse as detected by the accounting office.

The Development of Integrated Medical Services

A potentially large insurance scheme that is now being organized recognizes the limitations of an insurance plan as regards economy and high quality where the service is rendered by individual physicians on a fee-for-service basis. This scheme, therefore, proposes to provide the medical service through groups of physicians-organized about hospitals. The success of the plan would appear to depend largely on two things. First, will the medical profession participate in the organization of such group services to be administered and integrated through executive committees of hospitals and their staffs? Second, will the public appreciate and accept the medical services of such groups rather than the services of individual physicians? The answer to the latter question will probably be "Yes." The answer to the former will depend largely on how extensively these organized groups of physicians can be made to include the majority of physicians in the area covered by the service. The problem involves the so-called "closed" or "open" aspect of hospital staffs. It seems clear that there will have to be well considered compromise between the two extremes of staffs closed to but a few doctors and open to all. However, if an adequate administrative or executive control body can be established for each hospital group, even teaching hospitals should be able to open their staffs appreciably without jeopardizing their standards or teaching functions.

The utilization of such group hospital units in the provision of medical care under medical-insurance schemes would provide certain definite advantages. Picture the potentialities of a community medical service emanating from the well integrated salaried staff and hospital facilities of the New York, the Presbyterian, the Bellevue, the Johns Hopkins, the New Haven or the Massachusetts General Hospital financed by insurance payments for the employed, government payments for the indigent and complementary voluntary contributions, the last being used primarily to foster advances and improvement in medical care. Reasonably sound calculations indicate that physicians' salaries of \$3000 to \$15,000 a year could be provided. The intermittent services of ward and outpatient physicians would be corrected. The lack of integration between inpatient and outpatient and home care would no longer be inevitable. The control of the functions of the co-operating physicians by the administrative committee would permit an opening of the staff without jeopardizing its standards. This extension of hospital staffs under controlled supervision would in

itself raise the quality of medical care in no little degree.

Such a development of group services about hospitals fits in with the Hill-Burton bill for extending and integrating hospital facilities. This proposed legislation would provide a type of service under a national health program, such as proposed by the Wagner-Murray-Dingell bill, that would limit many of the dangers inherent in governmental participation in the financing of medical care. It would maintain control of medical service at the local level by the existing units of medical service that have, under the present system, demonstrated their value in both medical education and medical practice.

Should teaching hospitals be properly incorporated into any such insurance scheme, they would receive an income for services rendered that should cover the cost of these services and thus alter the hospitals' character as charity institutions. Since no medicine is more expensive than cheap medicine, it is essential that this income be sufficient to cover adequately the costs of both hospital and professional services. A clear distinction between these two categories of service and the allocation of specified charges for payment of physicians seems highly desirable to avoid exploitation of physicians by institutions. The result of inclusion of house-officer services among the professional services to be remunerated would be that young interns and residents would receive more adequate salaries than pertain today and that the cost of medical education would thus be reduced. Further elimination of the present financial barrier to entering the medical profession might be accomplished by provision of federal loans to needy students on a simple, businesslike basis. The loan would be granted to qualified applicants on the basis of repayment by working in government hospitals or other medical services. Such a logical stipulation would prevent abuse of the privilege. The Government's risk would be little, and benefit would be great. The services of these physicians in governmental institutions would improve the quality of their staffs and make their conversion to teaching institutions possible. Should this occur, improvement in the quality of service would follow almost axiomatically. Such a financing of medical education would benefit society and student alike.

The adequate financing of research and of medical education in general deserves, of course, a consideration that will remove both of these from a precarious dependence on philanthropy.

Whether the major portion of the funds collected under insurance plans be the result of voluntary association or of legislation, the responsibility placed on the administrative agencies for their wise disbursement should be stressed. An increase in the collection of funds for medical needs does not in

itself assure improvement in the financing of medical care.

To some persons such a development of group service by hospitals and their staffs as indicated here may appear utopian. Let it be appreciated, however, that failure to provide for the development and utilization of such services under any extensive insurance scheme may destroy the very medical units from which the past improvement in medical care has emanated and on which future progress depends. Such being the case, it appears to be of concern to those interested in better medical care — doctors and laymen alike — to see that provision for the utilization and development of such services is included in any state or national health plan.

An orderly plan of financing and operating an efficient system of providing medical care should neither be damned as impractical nor hailed as the millennium. The resources made available by the one and the quality of care attained by the other will depend on a manifestation of the qualities that have brought medicine to its present high level. Lessening the occasion for charity and the limitations incident to it should provide a wider, not a narrower, field for the idealism that has under unfavorable circumstances sustained charity medicine in the past.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M D, *Editor*

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 32081

PRESENTATION OF CASE

A seventy-three-year-old man was admitted to the hospital in an unconscious state

According to his wife he had been in good health except for hypertension of about ten years' duration. Ten months before admission he had a "stroke," with paralysis of the left side of the face followed by partial recovery. One and a half hours before admission he returned home from a walk and collapsed, being found unconscious.

Physical examination revealed a slightly cyanotic, restless man with cold hands and feet. The pupils were small and equal. The eyegrounds were not remarkable. The right elbow was stiff. The left leg was smaller than the right. The cardiac rhythm was irregular, with an apical systolic murmur. The lungs were clear. The liver was questionably enlarged. The right knee jerk was more active than the left. The Babinski sign was absent on both sides.

The temperature was 98°F, the pulse 150, and the respirations 30. The blood pressure was 110 systolic, 65 diastolic.

The white-cell count was 16,500. The urine contained no sugar. An electrocardiogram revealed auricular fibrillation, with a rate of 90, and evidence of left-axis deviation. ST₁ and ST₂ were depressed, as were ST₄ and ST₅, T₁, T₂, T₃, and the T wave in CF₂ were upright, the T wave in CF₄ and CF₅ was diphasic.

The patient remained unconscious, cyanotic and dyspneic. Two hours after admission he was given oxygen, as well as 3 cc of Cedilanid intravenously. The respirations became somewhat more regular, but the patient became restless and violent. Three cubic centimeters of paraldehyde was administered. The blood pressure fell to 80 systolic, 40 diastolic. The cyanosis increased. A unit of plasma was given intravenously. The heart sounds became distant, and the respirations assumed a Cheyne-Stokes character. After a short episode of tachycardia the patient expired, three hours after admission.

DIFFERENTIAL DIAGNOSIS

DR ALAN R MORITZ* In a conference of this kind it is unusual to have a pathologist make the ante-mortem diagnosis. His position is generally a little more secure than mine is at the moment.

When an apparently healthy seventy-three-year-old man has an unexpected syncopal attack and dies shortly thereafter without regaining consciousness, the cause is usually found to be either a cerebral vascular accident or an acute coronary insufficiency. Am I correct in assuming that there was no reason to suspect that head injury had anything to do either with his collapse or with his subsequent death? When and where did he collapse and did anyone see him fall?

DR GEORGE C COTZIAS He was at home and apparently was found lying on the bathroom floor.

DR MORITZ How long had he been unconscious before he was found?

DR COTZIAS No one knew how long he had been there, although they thought that it was probably less than half an hour.

DR MORITZ The reason I ask where the patient was found is that it is not particularly unusual for a person to strike his head when he falls as a result of a syncopal attack. Even though he may not have sustained a visible injury to the skull, subdural bleeding, sometimes bilateral, is often found at autopsy. I cannot be sure that that did not happen to this patient, but if it did, I regard it as an incident to the affair and not serious.

I am discarding cerebral apoplexy. I should be surprised if this man had collapsed and died as a result of intracerebral hemorrhage without sufficient clinical evidence to have at least warranted a lumbar puncture. I am reading between the lines a little bit in passing over this cerebral hemorrhage as I have, and I may not be justified in so doing. If I am wrong, my fault is in having too much confidence in the house officers. It does not appear that the patient manifested any signs or symptoms of cerebral disturbance that could not have been accounted for on a basis of circulatory failure. According to my clinical colleagues the electrocardiographic changes indicate coronary insufficiency. Am I correct in believing that there was no history suggestive of previous anginal attacks?

DR COTZIAS The history gave no evidence of angina.

DR MORITZ It is not at all uncommon for persons who have never complained of angina to die unexpectedly of coronary disease. Does the protracted period of unconsciousness that this man had between his initial seizure and his death detract from the diagnosis of acute coronary insufficiency? Considering his age I do not believe that it does. It is true that a young or middle-aged man is likely to die very quickly after the onset of an attack of coronary insufficiency of sufficient severity to cause

*Professor of legal medicine, Harvard Medical School

syncope It is not infrequent, however, for older men to survive such episodes of coronary insufficiency Perhaps the presence of cerebral arteriosclerosis predisposes to loss of consciousness following a relatively small impairment of the systemic circulation

I am somewhat disturbed at the extreme restlessness of this patient His agitation was of such duration and violence as to require paraldehyde sedation Although I know of no incompatibility between restless unconsciousness and the kind of cerebral anoxia that might result from coronary insufficiency, I must confess that I have never personally encountered so protracted a period of motor stimulation due to central circulatory failure Of course brief agonal convulsive seizures frequently precede death from coronary disease, and restless unconsciousness or convulsions are often reported in the Stokes-Adams syndrome I am willing then with some misgiving to accept the restlessness as an unusual but nevertheless plausible complication of circulatory failure caused by coronary insufficiency

To me the leukocytosis is best explained as a reaction to a myocardial infarct that was probably present for some hours before the occurrence of the terminal syncopal attack It appears that this recent infarct was at first asymptomatic Perhaps his collapse and death were due to tamponade caused by rupture of the heart at the site of a recent and previously asymptomatic infarct

DR. BENJAMIN CASTLEMAN Are there any further comments?

DR. PAUL D. WHITE The electrocardiogram is somewhat equivocal It is not normal It may indicate some disturbance in the circulation to the posterior wall of the left ventricle, but it is not typical of a posterior myocardial infarction There is no elevation of the ST segments in Leads 2 and 3, although there is considerable ST depression in Leads CF₁ and CF₂

DR. MORITZ I recognize that my clinical colleagues were at a disadvantage in expressing an opinion based on a description rather than on an examination of the electrocardiograms themselves

DR. WHITE They would not have been able to do much more had they seen the films The left-axis deviation could have gone with a hypertensive pattern, with the fibrillation due to cardiac irritability

DR. CHESTER M. JONES I should like to raise the question of the advisability of giving plasma in a patient with beginning cardiac failure It seems to me an unwise move The mere fact that the blood pressure fell is no indication for the administration of plasma in a case of this sort

DR. COTZIAS We believed that the picture of shock was more pronounced than the picture of heart failure

DR. WHITE We have often raised that question, whether patients with acute coronary occlusion in

shock may be helped by plasma We do not know

DR. JONES It is an important therapeutic decision to make in a case like this in which some harm might ensue

DR. WHITE It is conceivable that it might help if the myocardium has sufficient reserve

CLINICAL DIAGNOSIS

Myocardial infarction?

Cerebrovascular accident?

DR. MORITZ'S DIAGNOSES

Coronary thrombosis

Myocardial infarct

Rupture of myocardial infarct, with cardiac tamponade?

ANATOMICAL DIAGNOSES

Media necrosis aortica cystica, with rupture of aorta into pericardium.

Cardiac tamponade

PATHOLOGICAL DISCUSSION

DR. CASTLEMAN At autopsy the pericardium was filled with a liter of fresh unclotted blood It arose not from a tear of the myocardium, but from one of the ascending aorta The aortic lesion was not a dissecting aneurysm, however, but a complete through-and-through tear of an aorta that had the severest media necrosis cystica that we have ever seen It is the first case that we have had where the external rupture occurred simultaneously with the intimal tear, so that there was no chance for dissection

DR. WHITE There might have been some occluding pressure from the blood around the right coronary artery, which would explain the electrocardiographic changes

Where was the point of rupture?

DR. CASTLEMAN In the ascending aorta, about 1.5 cm above the valve

DR. WHITE Did slow bleeding occur before hemorrhage took place into the pericardium?

DR. CASTLEMAN I do not believe that the patient could have gone into syncope unless he had had a lot of bleeding at first If it were a slow leak, he probably would not have fallen He must have had a large rupture at the start and lived for four and a half hours

DR. WHITE Do you think that it all might have been due to tamponade?

DR. CASTLEMAN Yes, but he must have had a major break at the start to cause him to faint We have had a few patients with syphilitic aneurysms who have lived for some time after symptoms of rupture What is the sequence of events in your experience with ruptured aneurysm, Dr. Moritz? Do such patients often have a hiatus before they die?

DR. MORITZ We have had two or three who have I am surprised in this case that the man bled enough

into the pericardial sac to lose consciousness and yet was able to survive for three or four hours

DR WHITE Did he bleed in both directions along the aorta?

DR CASTLEMAN All along the adventitia of the aorta and the pulmonary artery The hemorrhage even extended along the adventitial coats of the smaller pulmonary arteries into the lung, a condition that we have seen before in patients with ruptured aortas

CASE 32082

PRESENTATION OF CASE

A forty-four-year-old Irish truck driver was admitted to the hospital complaining of shortness of breath, orthopnea and edema of the legs

Four years before admission he had been rejected by his draft board because of "heart disease" He remained symptomless, however, until fourteen months before admission, when he complained of weakness and fell while working Although he stopped work, he noticed, five months later, that he was gradually losing weight He developed anorexia, vomiting, abdominal pain, dyspnea and orthopnea He was digitalized and his symptoms subsided He was easily fatigued and had anterior chest pain on exertion Four months before admission he discontinued digitalis and resumed full-time work Soon, however, without any preceding trauma, infection or undue exertion, he noticed the sudden onset of extreme shortness of breath He also complained of pain in the anterior chest Two months later he again consulted his physician, who gave him more digitalis Three weeks before admission he was confined to bed, and two weeks later he entered another hospital, where he received digitalis and ammonium chloride After leaving the hospital of his own volition, he began to cough up small amounts of thin, bloody sputum, and swelling of the legs progressed rapidly For the two days before admission he had passed no urine

The past history revealed no evidence of rheumatic fever or venereal disease

Physical examination revealed a well developed and nourished man who was dyspneic, orthopneic and cyanotic He did not complain of pain Severe arteriosclerosis was apparent The fingers were clubbed The pupils were normal The neck veins were pulsating The heart was enlarged to the right and to the left, the left border being 12 cm from the midline in the fifth intercostal space The point of maximal impulse was in the anterior axillary line at the sixth interspace, with a forceful thrust A-Grade III diastolic murmur and a Grade I systolic murmur were heard at the apex, and both were transmitted to the axilla A Grade II diastolic murmur and a Grade I systolic murmur were heard over the aortic area The latter was transmitted to the

neck The aortic second sound was obliterated A diastolic thrill was palpable in the suprasternal notch The left lung was clear At the right base, fremitus was absent, breath sounds were diminished, and crackling inspiratory rales were heard, percussion revealed flatness over this area The abdomen apparently contained no fluid The liver edge was palpable four fingerbreadths below the right costal margin, it was firm, sharp, slightly tender and not pulsating The spleen was not felt The lower extremities showed marked pitting edema, which extended to the hips

The temperature was 97°F, the pulse 80, regular and full, and the respirations 20 The blood pressure was 115 systolic, 75 diastolic

The red-cell count was 4,900,000, with 14.6 gm of hemoglobin The white-cell count was 11,700 The urine was clear and acid, with a specific gravity of 1.017 It gave a +++ test for albumin, and the sediment contained 25 white cells, no red cells and many granular and hyaline casts per high-power field The nonprotein nitrogen was 31 mg per 100 cc, the total serum protein 5.2 gm, and the prothrombin time 30 seconds (normal, 18-20 seconds) A blood culture was negative

An x-ray film of the chest on admission revealed that the heart was large, especially in the region of the left ventricle, which was extended downward and laterally The cardiothoracic ratio was approximately 20/29.8 The left auricle was enlarged There were areas of calcification in the region of the mitral and aortic valves The hilar and pulmonary vessels were diffusely engorged, and both lungs were hazy There was a small amount of fluid in both pleural cavities There was a localized area of increased density in the right costophrenic sinus, which in the lateral view was seen to be round A similar area was seen somewhat higher in the right lower lobe in close contact with the interlobar septum

Three days after admission, the patient's edema had markedly subsided but the temperature continued to rise, reaching as high as 102°F Hemoptysis continued, and the liver remained enlarged The fluid in the right pleural cavity increased A friction rub was heard for a short time in the right axilla and then disappeared

Another chest film taken on the sixth hospital day showed hazy homogeneous density occupying the lower half of the right lung field and obscuring the outline of the diaphragm and heart Jaundice appeared on the eighth hospital day On the ninth hospital day, 1100 cc of bloody fluid was removed from the right pleural cavity It had a specific gravity of 1.012, with 37,000 red cells and 1700 white cells per cubic millimeter, 44 per cent of the latter being polymorphonuclear cells and 56 per cent lymphocytes The following day, after a period of fluttering, irregular heart action, the patient expired

DIFFERENTIAL DIAGNOSIS

DR. ROBERT S. PALMER On the basis of the physical findings, namely the orthopnea, dyspnea, cyanosis, edema and engorged liver, we feel sure that this forty-four-year-old man had congestive heart failure. There was a large heart with enlargement outward and downward, and at the apex there were a loud diastolic murmur and a slight systolic murmur. At the base there were a slight systolic murmur, transmitted to the neck, and a moderate diastolic murmur. The diastolic murmur at the apex may have been a murmur transmitted from the base. Aortic systolic murmurs may be heard at the apex but are less likely to be than are diastolic murmurs. The patient was rejected by his draft board four years previously, which may mean cardiac enlargement or murmurs at that time. I believe that this man had valvular heart disease, probably rheumatic, and although the characters of the murmurs are not well described, the apical murmurs are those of mitral stenosis and regurgitation. We must then consider aortic valvular disease and wonder, because of the obliteration of the aortic second sound and the transmission of the systolic murmur to the neck, if he did not have aortic stenosis. If he had aortic stenosis, on a statistical basis it was probably rheumatic. We know that one can rarely have pure calcareous valvular disease, Mönckeberg's sclerosis, but much oftener calcareous disease is superimposed on an old rheumatic lesion. Of course, calcareous disease is sometimes superimposed on a congenital valvular deformity, such as a bicuspid aortic valve. If we consider aortic stenosis, we should also consider congenital subaortic narrowing, which is sometimes confused with acquired aortic stenosis. One might also consider the possibility of syphilis. We are given no information about serologic tests, but because aortic stenosis rather than regurgitation is probable, it is unlikely that he had syphilitic valvular disease. Of course, if he had marked aortic valvular disease, the diastolic murmur at the apex could have been due to relative or functional mitral stenosis.

The history is consistent with these possibilities. We know that he was rejected by the draft board. Since there is no note of murmurs' having been heard during early life, we may exclude congenital lesions. Fourteen months before admission he experienced faintness or weakness, which is not infrequent in patients with aortic lesions, particularly an aortic stenosis. Nine months before admission he had anorexia, vomiting, abdominal pain and some shortness of breath, which are probably signs of visceral passive congestion. Evidently this was relieved by digitalis. Later he had sudden paroxysmal dyspnea, without preceding trauma or exertion. We have no observations of any change in the murmurs. I do not suspect a ruptured aortic cusp. Sudden paroxysmal dyspnea is of common occur-

rence in valvular disease, particularly aortic valvular disease, and I am inclined to think is especially frequent in patients with aortic stenosis. Later the patient got up and about, but after a period of partial disability he was put to bed with symptoms and signs of typical congestive heart failure. He was relieved by rest, diuretics and digitalis but finally was admitted to this hospital with recurrent congestive failure, having had anuria for two days.

In the x-ray film, the heart is apparently enlarged downward and outward, as one sees in cases of free aortic regurgitation. The patient, however, did not have the blood pressure of true aortic regurgitation. The general enlargement possibly went with congestive failure and dilatation of all chambers of the heart. The x-ray appearance of the heart is not the so-called "concentric hypertrophy" of pure aortic stenosis.

Subsequently the patient ran a fever. One blood culture was negative, and there is no evidence for making one think of subacute bacterial endocarditis superimposed on valvular disease, although it is possible that he may have a terminal endocarditis.

On the basis of the x-ray findings we are left with the same possibilities regarding the diagnosis of the valvular lesions. The enlargement of the left auricle leads one to believe that there was disease of the mitral valve, and in view of the murmurs at the apex, mitral stenosis and regurgitation seem likely. The outline of the heart, with the marked enlargement downward and outward, is enough to convince me that he had aortic valvular disease. Perhaps the moderate aortic diastolic murmur was transmitted to the apex, as it commonly is. The aorta was small. Free aortic regurgitation, even that due to rheumatic infection, is likely to show some aortic dilatation although the dilatation is usually more marked in syphilitic disease. So, with the aortic murmur, the absent aortic second sound and the transmission of the systolic murmur to the neck I think that this man had some degree of aortic stenosis. The x-ray finding of areas of calcification indicates that he also had calcareous valvular disease. There were two shadows in the lung fields, one at least in contact with the pleura. Although encapsulated pleural fluid and metastatic tumor are possibilities, I should imagine that the best explanation in this case is that these areas in the x-ray films represent pulmonary infarctions.

May we see the x-ray films?

DR. MILFORD D. SCHULZ These films show what the protocol stated. The areas of calcification are in the region of the mitral ring and in that of the aortic valve. The aorta is not large. Here is an area of increased density in the right posterior gutter that looks like an infarct. I do not know why he should have one.

DR. PALMER How about the other one in the interlobar septum?

DR SCHULZ I am not sure about it. The fluoroscopist must have had more information than we have here.

DR PALMER The shadows of pulmonary infarctions do not necessarily have to appear wedge-shaped, do they?

DR SCHULZ They do not, but they are usually in contact with two pleural surfaces, as this one is described as being.

On the film made six days following the first examination, there is marked increase in the density of the right lower chest, some of which is probably due to fluid in the pleural sinus.

DR PALMER Does this film show much evidence of pulmonary congestion?

DR SCHULZ Yes, the hilar shadows are large on both sides, and the pulmonary markings are prominent throughout.

DR PALMER Is the large left auricle a true observation?

DR SCHULZ In the lateral view it looks as if there is enlargement of the left auricle. In the antero-posterior view what enlargement there is of the left auricle is overshadowed by the ventricle.

DR PALMER Jaundice appeared on the eighth day, and bloody fluid was removed from the pleural cavity on the following day, both of which are consistent with pulmonary infarction.

I believe that this man had valvular heart disease, probably rheumatic in origin, with some aortic regurgitation and aortic stenosis and, because of the size of the left auricle as seen by x-ray, with mitral stenosis and regurgitation. I think that the history is explained by these findings, with accompanying passive congestion and terminal multiple pulmonary infarctions. I am interested in the clubbing of the fingers, and wonder how often clubbed fingers are found in cases of congestive heart failure. They occur with infection associated with heart disease, as in subacute bacterial endocarditis and in active rheumatic infection. From the textbooks I could find nothing about the occurrence of clubbing of the fingers in congestive heart failure. Congestive failure with cyanosis may give clubbing. I have also seen clubbing in people with neither heart disease, pulmonary disease or any other recognizable disease. I am not sure of the explanation of that one finding. I should like to know if anyone has seen it in patients with plain congestive heart failure without cyanosis.

DR TRACY B MALLORY Are there any questions or further discussion?

DR DONALD KING I have never seen clubbing of the fingers in plain congestive failure. I have seen a lot in lung disease.

DR PALMER In this case there is possibly another explanation of the clubbed fingers aside from the heart disease.

DR KING I should accept your diagnosis.

DR JAMES A TOWNSEND This heart was ex-

tremely large. I wonder if it suggests that the patient had a valvular lesion on the right as well as on the left.

DR PALMER If he had tricuspid disease, one would expect a really big and pulsating liver.

CLINICAL DIAGNOSIS

Rheumatic heart disease, with aortic and mitral stenosis

DR PALMER'S DIAGNOSES

Rheumatic heart disease
Aortic stenosis and regurgitation
Mitral stenosis and regurgitation
Congestive heart failure
Hypertrophy and dilatation of heart
General passive congestion
Multiple pulmonary infarction

ANATOMICAL DIAGNOSES

Calcareous aortic stenosis
Congenital bicuspid aortic valve?
Hypertrophy of heart
Chronic passive congestion
Pulmonary embolism
Infarcts of lung
Thrombophlebitis of leg veins

PATHOLOGICAL DISCUSSION

DR MALLORY The findings at autopsy were limited to the heart and lungs. The heart was extremely large, weighing 700 gm. The only lesion was in the aortic valve, which was markedly calcified. The mitral valve showed slight dilatation, measuring 12 cm in circumference, and was slightly larger than the tricuspid valve. All cavities of the heart shared in the dilatation, and all showed some degree of hypertrophy. The right pleural cavity contained nearly a liter of blood-tinged fluid. There was some fresh fibrin on the pleural surface, and in the right lower lobe there were numerous infarcts of varying size. The arteries leading to these areas of infarction contained emboli, a number of them showing advanced organization, so that I think we can feel certain that attacks of pulmonary embolism had been occurring over a period of some weeks before death. Perhaps all the symptoms of the last few weeks of life can be explained by a series of emboli.

The aortic-valve disease was of a type that one sees not infrequently, which strongly suggests origin from a congenital bicuspid valve. Two valves were completely fused at one commissure. The other commissures were quite normal. Heavily calcified masses filled the sinuses of Valsalva, and the calcification extended from the base of the cusps almost up to the very edge. The lumen was reduced to a V-shaped slit. I was unable to see anything on the mitral valve that I could definitely diagnose as rheumatic involvement, nor could I

DIFFERENTIAL DIAGNOSIS

DR ROBERT S PALMER On the basis of the physical findings namely the orthopnea, dyspnea, cyanosis, edema and engorged liver, we feel sure that this forty-four-year-old man had congestive heart failure. There was a large heart with enlargement outward and downward, and at the apex there were a loud diastolic murmur and a slight systolic murmur. At the base there were a slight systolic murmur, transmitted to the neck, and a moderate diastolic murmur. The diastolic murmur at the apex may have been a murmur transmitted from the base. Aortic systolic murmurs may be heard at the apex but are less likely to be than are diastolic murmurs. The patient was rejected by his draft board four years previously, which may mean cardiac enlargement or murmurs at that time. I believe that this man had valvular heart disease, probably rheumatic, and although the characters of the murmurs are not well described, the apical murmurs are those of mitral stenosis and regurgitation. We must then consider aortic valvular disease and wonder, because of the obliteration of the aortic second sound and the transmission of the systolic murmur to the neck, if he did not have aortic stenosis. If he had aortic stenosis, on a statistical basis it was probably rheumatic. We know that one can rarely have pure calcareous valvular disease, Mönckeberg's sclerosis, but much oftener calcareous disease is superimposed on an old rheumatic lesion. Of course, calcareous disease is sometimes superimposed on a congenital valvular deformity, such as a bicuspid aortic valve. If we consider aortic stenosis, we should also consider congenital sub-aortic narrowing, which is sometimes confused with acquired aortic stenosis. One might also consider the possibility of syphilis. We are given no information about serologic tests, but because aortic stenosis rather than regurgitation is probable, it is unlikely that he had syphilitic valvular disease. Of course, if he had marked aortic valvular disease, the diastolic murmur at the apex could have been due to relative or functional mitral stenosis.

The history is consistent with these possibilities. We know that he was rejected by the draft board. Since there is no note of murmurs having been heard during early life, we may exclude congenital lesions. Fourteen months before admission he experienced faintness or weakness, which is not infrequent in patients with aortic lesions, particularly an aortic stenosis. Nine months before admission he had anorexia, vomiting, abdominal pain and some shortness of breath, which are probably signs of visceral passive congestion. Evidently this was relieved by digitalis. Later he had sudden paroxysmal dyspnea, without preceding trauma or exertion. We have no observations of any change in the murmurs. I do not suspect a ruptured aortic cusp. Sudden paroxysmal dyspnea is of common occur-

rence in valvular disease, particularly aortic valvular disease, and I am inclined to think is especially frequent in patients with aortic stenosis. Later the patient got up and about, but after a period of partial disability he was put to bed with symptoms and signs of typical congestive heart failure. He was relieved by rest, diuretics and digitalis but finally was admitted to this hospital with recurrent congestive failure, having had anuria for two days.

In the x-ray film, the heart is apparently enlarged downward and outward, as one sees in cases of free aortic regurgitation. The patient, however, did not have the blood pressure of true aortic regurgitation. The general enlargement possibly went with congestive failure and dilatation of all chambers of the heart. The x-ray appearance of the heart is not the so-called "concentric hypertrophy" of pure aortic stenosis.

Subsequently the patient ran a fever. One blood culture was negative, and there is no evidence for making one think of subacute bacterial endocarditis superimposed on valvular disease, although it is possible that he may have a terminal endocarditis.

On the basis of the x-ray findings we are left with the same possibilities regarding the diagnosis of the valvular lesions. The enlargement of the left auricle leads one to believe that there was disease of the mitral valve, and in view of the murmurs at the apex, mitral stenosis and regurgitation seem likely. The outline of the heart, with the marked enlargement downward and outward, is enough to convince me that he had aortic valvular disease. Perhaps the moderate aortic diastolic murmur was transmitted to the apex, as it commonly is. The aorta was small. Free aortic regurgitation, even that due to rheumatic infection, is likely to show some aortic dilatation although the dilatation is usually more marked in syphilitic disease. So, with the aortic murmur, the absent aortic second sound and the transmission of the systolic murmur to the neck I think that this man had some degree of aortic stenosis. The x-ray finding of areas of calcification indicates that he also had calcareous valvular disease. There were two shadows in the lung fields, one at least in contact with the pleura. Although encapsulated pleural fluid and metastatic tumor are possibilities, I should imagine that the best explanation in this case is that these areas in the x-ray films represent pulmonary infarctions.

May we see the x-ray films?

DR MILFORD D SCHULZ These films show what the protocol stated. The areas of calcification are in the region of the mitral ring and in that of the aortic valve. The aorta is not large. Here is an area of increased density in the right posterior gutter that looks like an infarct. I do not know why he should have one.

DR PALMER How about the other one in the interlobar septum?

DR SCHULZ I am not sure about it The fluoroscopist must have had more information than we have here

DR PALMER The shadows of pulmonary infarctions do not necessarily have to appear wedge-shaped, do they?

DR SCHULZ They do not, but they are usually in contact with two pleural surfaces, as this one is described as being

On the film made six days following the first examination, there is marked increase in the density of the right lower chest, some of which is probably due to fluid in the pleural sinus

DR PALMER Does this film show much evidence of pulmonary congestion?

DR SCHULZ Yes, the hilar shadows are large on both sides, and the pulmonary markings are prominent throughout

DR PALMER Is the large left auricle a true observation?

DR SCHULZ In the lateral view it looks as if there is enlargement of the left auricle In the antero-posterior view what enlargement there is of the left auricle is overshadowed by the ventricle

DR PALMER Jaundice appeared on the eighth day, and bloody fluid was removed from the pleural cavity on the following day, both of which are consistent with pulmonary infarction

I believe that this man had valvular heart disease, probably rheumatic in origin, with some aortic regurgitation and aortic stenosis and, because of the size of the left auricle as seen by x-ray, with mitral stenosis and regurgitation I think that the history is explained by these findings, with accompanying passive congestion and terminal multiple pulmonary infarctions I am interested in the clubbing of the fingers, and wonder how often clubbed fingers are found in cases of congestive heart failure They occur with infection associated with heart disease, as in subacute bacterial endocarditis and in active rheumatic infection From the textbooks I could find nothing about the occurrence of clubbing of the fingers in congestive heart failure Congestive failure with cyanosis may give clubbing I have also seen clubbing in people with neither heart disease, pulmonary disease or any other recognizable disease I am not sure of the explanation of that one finding I should like to know if anyone has seen it in patients with plain congestive heart failure without cyanosis

DR TRACY B MALLORY Are there any questions or further discussion?

DR DONALD KING I have never seen clubbing of the fingers in plain congestive failure I have seen a lot in lung disease

DR PALMER In this case there is possibly another explanation of the clubbed fingers aside from the heart disease

DR KING I should accept your diagnosis

DR JAMES A TOWNSEND This heart was ex-

tremely large I wonder if it suggests that the patient had a valvular lesion on the right as well as on the left

DR PALMER If he had tricuspid disease, one would expect a really big and pulsating liver

CLINICAL DIAGNOSIS

PATHOLOGICAL DISCUSSION

DR MALLORY The findings at autopsy were limited to the heart and lungs The heart was extremely large, weighing 700 gm The only lesion was in the aortic valve, which was markedly calcified The mitral valve showed slight dilatation, measuring 12 cm in circumference, and was slightly larger than the tricuspid valve All cavities of the heart shared in the dilatation, and all showed some degree of hypertrophy The right pleural cavity contained nearly a liter of blood-tinged fluid There was some fresh fibrin on the pleural surface, and in the right lower lobe there were numerous infarcts of varying size The arteries leading to these areas of infarction contained emboli, a number of them showing advanced organization, so that I think we can feel certain that attacks of pulmonary embolism had been occurring over a period of some weeks before death Perhaps all the symptoms of the last few weeks of life can be explained by a series of emboli

The aortic-valve disease was of a type that one sees not infrequently, which strongly suggests origin from a congenital bicuspid valve Two valves were completely fused at one commissure The other commissures were quite normal Heavily calcified masses filled the sinuses of Valsalva, and the calcification extended from the base of the cusps almost up to the very edge The lumen was reduced to a V-shaped slit I was unable to see anything on the mitral valve that I could definitely diagnose as rheumatic involvement, nor could I

find any microscopic evidence of rheumatic infection in the myocardium. On the other hand, I realize that I am a prejudiced party on this issue. I can rarely find microscopic evidence of rheumatic involvement in a case of calcareous aortic stenosis, whereas other pathologists find it quite often.

DR CHARLES S. KUBIK: Did you find a source for the emboli?

DR MALLORY: There were numerous thrombi in

the leg veins. The larger veins were free, but when we cut into the muscles of the calf, the intramuscular vessels were thrombosed and there was some degree of myositis of these calf muscles as well. I personally think that the onset of jaundice was connected with the pulmonary infarction. Any great degree of jaundice is unusual with simple congestive failure, but with the onset of pulmonary infarction it becomes almost the rule rather than the exception.

COMMUNICATIONS should be addressed to the *New England Journal of Medicine*, 8 Fenway, Boston 15, Massachusetts

RATION'S END?

WE ARE being prepared, at the time of this writing, for the abandonment of sugar rationing at some time in the not too distant future, and with it the ending of the entire food rationing program. This does not necessarily indicate an abundance of sugar on the way, any more than the removal of restrictions on other foods has been followed by a surfeit of the market with them, — butter and margarine are currently not to be found in the local stores, — nor does it mean that we shall be living hereafter in a land of corn and wine, whatever definition may be given to the former word in this particular. It does mean that soon a Cuban and later a Philippine crop of sugar will place this article of food in the ranks of others supposed to be reasonably plentiful, and the

members of medical advisory committees may end their tasks with heads unbowed, if bloody.

Sugar, as a rationed commodity, has rarely been found by the Medical Advisory Committee to the Regional Office of Price Administration to be required in larger quantities than those allowed by basic rationing. Other sugars and other forms of carbohydrate have been too easily available, and there are few diseases, if any, that require cane sugar in their treatment. It is therefore at least of interest to note the numbers of persons uncovered since local rationing boards went out of existence who have been receiving extra allotments of sugar, apparently without benefit of approval by any medical advisory committee. In fact, a recent report from the Regional Office of Price Administration since the files from the state have been consolidated, indicates that more than 2000 persons in Massachusetts have regularly been receiving extra sugar since 1942, of which number only a very small fraction had ever had their requests reviewed, as required by regulation, by a medical advisory committee. No one had realized how much sweetness was being wasted on the desert air!

Two thousand out of a population of 4,316,721 is no great matter, and we might, indeed, consider with amazement the fact that so few have owed so little to so many. In our sturdy democracy, however, where each rationing board might well have sought to be a law unto itself, we now wonder, idly, how many other importunate persons may have owed their teeming fleshpots to a local handout.

WAIVER OF DISABILITY

ATTENTION is called to a letter published elsewhere in this issue of the *Journal* in which the commanding officer of an overseas station hospital clarifies a misunderstanding concerning the so-called "waiver of disability" on the part of an officer entering the armed services of the United States. There can be no doubt that it is generally believed that, if a man or woman accepts a commission in the Armed Services and at the same time has a physical defect that can serve as a source of future trouble, he expects, as part of the sacrifice he must make for his country, to "sign a waiver," which will

release the Government from all responsibility for the care of conditions subsequently arising out of the disability that has been waived

Such a belief seems to be entirely wrong. If the author of the letter is correct, — and there is no reason to suppose that he is not, — this false belief is based on an equally erroneous misconception. It is the Government that does the "waiving." By so doing it does not deprive the physically defective officer of his right to obtain redress for disablement arising in the line of duty even though it may be secondary to his disability. Instead, the Government assumes the risk and "accepts the person in spite of the defect."

This is an important point, and one that should be drawn to the attention of all veterans. From conversations heard here and there it is apparent that there are a considerable number of disabled veterans who think that they are not entitled to apply for benefits from the Government because they waived their rights to make such application when they entered the service. Veterans' organizations should publicize this mistake so that it can be corrected at once. Such veterans should be no longer deprived of the help that they may need badly and are certainly entitled to.

MASSACHUSETTS MEDICAL SOCIETY

DEATHS

MULLIGAN — Francis J. Mulligan, M.D., of Newton, died February 5. He was in his forty-fifth year. Dr. Mulligan received his degree from Boston University School of Medicine in 1928. He was Newton school physician and a member of the staff of the Newton-Wellesley Hospital. His widow, four sisters and a brother survive.

STEVENS — Harry L. Stevens, M.D., of New Bedford, died January 29. He was in his seventy-sixth year. Dr. Stevens received his degree from Baltimore Medical College in 1891. He was formerly physician to the overseer of the poor and city physician. In 1936 he was appointed to a seven-year term on the State Board of Registration in Medicine.

TIMMINS — Edward F. Timmins, M.D., of South Boston, died December 11. He was in his sixty-fifth year.

Dr. Timmins received his degree from Harvard Medical School in 1904. He served for many years as medical inspector of the South Boston district and supervising physician for the Boston School Department. He was a member of the South Boston Medical Club, of which he had been president. He became a fellow of the Massachusetts Medical Society in 1911 and first served as councilor in 1936; he was subsequently appointed to the Committee to Study the Practice of Medicine by Unregistered Persons and was elected a censor by his district society in 1944.

His widow, two sons and two daughters survive.

MASSACHUSETTS MEDICAL SOCIETY POSTWAR LOAN FUND

The Postwar Loan Fund has been set up, and all discharged medical officers who were members of the Massachusetts Medical Society in good standing at the time of their entry into the service may apply for loans from this fund. For further information apply to:

George L. Schadt, Chairman
Postwar Loan Fund
8 Fenway
Boston 15, Massachusetts

WOODWARD — Samuel B. Woodward, M.D., of Worcester, died January 29. He was in his ninety-third year.

Dr. Woodward received his degree from Harvard Medical School in 1878. He spent more than two years studying abroad. For many years he was consulting and visiting surgeon at St. Vincent and Worcester City hospitals. He was a trustee of Worcester State Hospital and chairman of its board of trustees. He was a former president of the Massachusetts Medical Society and also of the Alumni Association of Boston City Hospital. He was a fellow of the American Medical Association and of the American Academy for the Advancement of Science. He retired in 1921 after forty years of practice.

NEW HAMPSHIRE MEDICAL SOCIETY

SCOTT — Nathaniel H. Scott, M.D., of Wolfeboro, died January 25. He was in his ninety-fifth year.

Dr. Scott received his degree from Bowdoin Medical School, Maine, in 1874. He had practiced general medicine and surgery in Wolfeboro from 1880 until his retirement about twenty years ago.

His widow, a son and five daughters survive.

MISCELLANY

DEPARTMENT OF ANESTHESIA AT MCGILL

The Department of Anesthesia has recently been created at McGill University, according to Dr. Wesley Browne, chairman of the department. Its stated objectives are as follows: to improve the teaching of anesthesia to the undergraduate student in medicine; to enhance the opportunities for learning anesthesia by the interns of the hospitals connected with the University; to maintain a three-year diploma course in anesthesia for those graduates in medicine who desire to become specialists; and to develop investigation in anesthesia, both within the department, correlating the clinic and the laboratory, and in co-operation with other departments of the University.

AMERICAN BOARD OF OPHTHALMOLOGY

In regard to the substitution of a preceptorship for residency in an ophthalmic hospital, Dr. S. Judd Beach, secretary of the American Board of Ophthalmology states that the Board has always accepted such training in favorable cases. It should, however, be pointed out that neither a residency nor a preceptorship suffices in itself to meet the requirements of the Board. Each case will still be judged on its merits in

In entering on a preceptorship, certain conditions should be kept in mind. First the student will profit most after a sound course in the basic sciences of the eye and of vision, such as optics, physiology, pathology, bacteriology, chemistry, pharmacology, anatomy, embryology and neurology, and in the relation of the eye to general disease. This is essential for a residency, more so for a preceptorship.

Although men have been accepted from preceptors not diplomates of the Board, it is obvious that the Board has more information about those teachers who have passed its examinations. Any preceptor should understand that he is assuming a responsibility in taking a student and is not merely obtaining help in the drudgery of his office. He should be willing to give time to clinical training and the use of apparatus, such as the slit-lamp, ophthalmoscope and tonometer, and to directing the student's practice in surgery on animal eyes, assisting in operations and ultimately in the performance of them.

To cover the same amount of ground will take much longer in a preceptorship than in a residency, and students should accept opportunities to take hospital positions of all sorts as they become available.

CORRESPONDENCE

WAIVER OF DISABILITY AND THE ARMY'S NEED FOR SENIOR MEDICAL OFFICERS

To the Editor: Reference is made to the letter "An Appeal," signed by W. A. R. Chapin, that appeared in the October 4, 1945, issue of the *Journal*. In this letter I note the statement that the medical officer in question "waived a disability." This is an error that is widespread and should be corrected.

For nearly three years I was on the staff of the surgeon of one of the nine service commands in the Continental United States, during which time I was the sole arbiter of who was or was not physically qualified for military service. This period covered the expansion of the armed forces, which began in September, 1940. I therefore speak with a detailed and accurate knowledge of the factors involved.

No officer ever waived or signed a waiver of his physical defects. Late in 1941, for reasons not clear to me, the War Department adopted certain policies in the case of officers who had defects that technically disqualified for military service. Briefly stated the policy was to require an officer who was found to have certain defects to sign a certificate admitting the presence of the defect and requesting that the defect be waived for the purpose of entering on active duty. If the reviewing authority decided that the defect did not constitute a bad military risk he (the reviewing authority) accepted the officer for general or limited military service and waived the defect for the Government. The subject officer waived nothing!

One cannot legally waive a defect that he or she may have. There are Supreme Court decisions on this, which may be briefly summarized as follows: The right to compensation is a statutory right and as such cannot be waived by a person as a condition of employment by or service in the armed forces. In other words, a defect existing prior to entry into the service, which becomes aggravated to a disabling degree by reason of service in the armed forces, is compensable just as though the defect were incurred by reason of such service. Thus, by waiving the defect, or more correctly, by accepting the person in spite of the defect, the Government assumes the risk.

I shall not attempt to pass judgment on the complaint offered by the officer who wrote the letter, but I must speak in defense of the Army. I believe that I am qualified, since I have been in command of a large hospital out here for almost two years.

In the mad rush to get physicians out of the Army the hospitals in the Pacific are being stripped of competent professional personnel. Transfer of medical officers with high-point scores removes the most competent ones. The low-point men who remain are, almost without exception, rather recent graduates with no qualifications in any specialty. As matters now stand, I shall lose my chiefs of medicine and surgery in January, and so far as I now know, they will of necessity have to be replaced by young men who have no special qualifications for such vitally responsible positions. What recognized civilian hospital would accept as a consultant in surgery a physician who had graduated in 1942, had served a nine-month internship and had then acted as a

ward surgeon or assistant for two years? The answer is obvious, but that is exactly the situation we are now confronted with out here. The consequences may well result in a Congressional investigation that could not fail to reflect unpleasantly on the profession.

This station hospital is now part of the permanent garrison on an island that is (or was) an integral part of the Japanese Empire. I am not a Regular Army officer but an old reservist from the last war who has been on active duty for more than five years and who has volunteered to remain out here until April 1, 1946, in an effort to reorganize this hospital with such personnel as is available. I have had an almost complete turnover of personnel since V-J Day, and within the next six weeks I shall be the only person left in this organization who was in it at that time. Most of the personnel are "fresh out from the States."

There are two sides to every question. This matter is particularly difficult, especially for those of us in command positions.

COLONEL _____, M.C., A.U.S.
Commanding

NOTICES

ANNOUNCEMENTS

Dr. F. Dennette Adams has returned from military service and resumed the practice of internal medicine at 226 Marlborough Street, Boston 16.

Dr. Robert H. Barker, having returned from service in the United States Navy, is resuming the practice of obstetrics and gynecology at 330 Dartmouth Street, Boston.

Dr. Martin A. Berezin, having returned from active service with the United States Army Medical Corps, announces the opening of his office at 117 Bay State Road, Boston, for the practice of psychiatry and neurology.

Dr. J. Charles Drooker, having recently completed military service in the United States Army, is resuming the practice of diseases of the ear, nose and throat at Hotel Gralyn, 20 Charlesgate West, Boston.

Dr. Robert H. Goodwin, having returned from active duty in the United States Navy, is resuming the practice of obstetrics and gynecology at 15 South 6th Street, New Bedford.

Dr. Ward I. Gregg announces his return from military service and the reopening of his office for the practice of gynecology and surgery at 266 Beacon Street, Boston.

Dr. Thomas M. Hearne, having been released from active duty with the United States Navy, announces the reopening of his office at 43 Stratford Road, Melrose, for the practice of medicine and obstetrics.

Dr. I. H. Jaffee, having returned from active service with the United States Army, announces the opening of his office at 483 Beacon Street, Boston, for the practice of allergy.

Dr. Allen S. Johnson announces his return from service with the United States Navy and the opening of an office at 276 Bridge Street, Springfield.

Dr. James J. Regan has resumed the practice of ophthalmology at 520 Commonwealth Avenue, Boston.

Dr. Henry R. Viets announces the removal of his office from 262 Beacon Street to 20 Gloucester Street, Boston.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING THURSDAY, FEBRUARY 28

FRIDAY, MARCH 1
*10:00 a.m. - 12:00 p.m. Medical Staff Rounds. Peter Bent Brigham Hospital
10:50 a.m. Systemic Therapy of Skin Conditions. Dr. George E. Morris. (Postgraduate Clinic in Dermatology and Syphilology) Amphitheater. Dowling Building. Boston City Hospital
MONDAY, MARCH 4
*12:00 p.m. - 1:00 p.m. Clinicopathological Conference. Peter Bent Brigham Hospital

MEDICAL SHOCK. ABNORMAL BIOCHEMICAL CHANGES IN PATIENTS WITH SEVERE, ACUTE MEDICAL ILLNESSES, WITH AND WITHOUT PERIPHERAL VASCULAR FAILURE*

CHARLES S. DAVIDSON, M.D.,† JESSICA H. LEWIS, M.D.,‡ HENRY J. TAGNON, M.D.,§

MARGARET A. ADAMS, A.B.,¶ AND F. H. L. TAYLOR, Ph.D.||

BOSTON

RECENT studies in the so-called "shock syndrome" in animals have definitely associated this syndrome with certain biochemical abnormalities.^{1,2} Hyperglycemia, lactic acidemia, lowered alkaline reserve and changes in the partition of the nonprotein nitrogen of the blood plasma have been reported in this condition. In hemorrhagic shock, increases in the plasma alpha amino nitrogen have recently been reported.^{3,4} Anoxia has been a frequent finding in shocked animals, and furthermore, anoxic anoxia itself has been found to produce some of the biochemical changes attributed to shock.

Recent reports from this laboratory have shown that in man marked biochemical changes of a similar nature to those reported in animals occur following thermal burns.^{5,6} Such changes were found to be significantly associated with the severity of the thermal injury and the presence of shock. Aub⁷ has reported abnormalities of carbohydrate metabolism following trauma.

The present investigation was undertaken to study the relation of peripheral vascular failure, uncomplicated by traumatic conditions, to the biochemical changes previously reported in shocked animals and following injury in man. The subjects used were patients suffering from severe medical illnesses, with or without the presence of peripheral vascular failure. In all cases there was no indication in the history that clinical diabetes was present.

METHODS

Twelve patients suffering from severe illnesses were studied. Their ages ranged from nineteen to eighty, 9 patients being over fifty years of age. There were 7 males and 5 females. No patient gave a history or had clinical evidence of diabetes mellitus. Five patients were admitted with severe infections, 4 with severe cardiovascular involvement, 1 of whom suffered from pneumococcus (Type 1) pericarditis, 2 following the ingestion of poison, probably an overdose of a barbiturate, and 1 with a massive gastric hemorrhage. Ten patients had some degree of peripheral vascular failure, the degree being estimated independently by two physicians. The criteria used in estimating the degree of failure are shown in Table 1. The essential details of the cases studied are given in Table 2. The patients were treated by specific or symptomatic therapy in accordance with the requirements of their clinical condition. Where such therapy had a bearing on the biochemical changes encountered it is commented on in the appropriate place in the text. Autopsies were obtained on certain patients who died, and the significant findings are stated in the text.

Blood and urine samples were obtained during and following the period of circulatory failure and analyzed for glucose (Somogyi-Benedict method), lactic acid, carbon dioxide content or combining power, alpha amino nitrogen (ninhydrin method) and oxygen. Tolerance for glucose was frequently determined by the intravenous method.⁸ Prothrombin times, icterus indices and hemoglobin levels were determined. The methods used for the various determinations have been stated elsewhere.⁶

RESULTS

The over-all data are presented in Table 3. They are arranged in order of decreasing lactic acid concentration in the blood plasma or serum. To arrive at the designation of the degree of peripheral

vascular failure, the clinical criteria given in Table 1 were used without reference to the biochemical findings. The data chosen for the construction of the table were those obtained at a time when the peripheral vascular failure was present to the greatest extent. Variations in the blood chemical findings in certain typical patients are presented in the figures.

The Relation of Biochemical Abnormalities to the Presence of Peripheral Vascular Failure

Abnormalities in carbohydrate metabolism. Hyperglycemia was found in 9 of the 10 patients showing some degree of peripheral vascular failure. The tenth patient was poorly nourished. There was

Lactacidemia was found in all patients showing any degree of peripheral vascular failure, regardless of the clinical diagnosis. The correlation between the concentration of lactic acid in the circulating blood and the degree of peripheral vascular failure was striking. As might be predicted, in general the carbon dioxide content or the combining power varied inversely with the lactacidemia, although there was no evidence that the change in the alkaline reserve varied quantitatively with the amount of lactic acid. Other fixed organic acids were not determined. The lactic acid levels ranged from 4 to 20 milliequiv per liter of plasma or serum. In 2 cases (Cases 8 and 10) in which no peripheral

TABLE 1 *Criteria Used in Estimating the Degree of Peripheral Vascular Failure**

DEGREE OF PERIPHERAL VASCULAR FAILURE	RESPIRATION†	PULSE*	BLOOD PRESSURE	MENTAL STATE	CYANOSIS	EXTREMITIES	OLIGOURIA
Minimal (+)	Normal	Thready and rapid	Slight fall	Restless and apprehensive	Lips or extremities or both	Pale and cool	None
Moderate (++)	Rapid and shallow	Thready and rapid	80/60 to 60/40	Apprehensive and confused	Lips or extremities or both	Cold and clammy	Questionable
Marked (+++)	Often Cheyne-Stokes or sighing	Thready and rapid	60/40 to 40/20	Confused to stuporous	Lips or extremities or both	Cold and clammy	Slight
Extremely marked (++++)	Often Cheyne-Stokes or sighing	Rapid, slow or unobtainable	40/0 to 20/0	Stuporous to comatose	Extremities mottled (extensive)	Cold and clammy	Moderate (often albumin, red cells and casts)

*Temperature, nausea and vomiting were not used as general criteria because of the fluctuations due to causes other than peripheral vascular failure. The effect of the duration of the failure was taken into consideration in evaluating the biochemical findings (see Table 3).

†Unless modified by the clinical condition—for example, pneumonia.

minimal or no elevation of the blood glucose in the 2 patients in whom peripheral vascular failure was absent. One of these patients (Case 8) suffered from streptococcal pneumonia and recovered. The other (Case 10) was poisoned, presumably by barbiturates, and subsequently died.

There was no correlation between the height of the blood glucose and the degree of peripheral vascular failure. In 3 cases (Cases 3, 4 and 11) this type of comparison was impossible because of the necessity of administration of glucose for therapeutic reasons.

Glucose-tolerance determinations were made in 8 patients. In the patients who survived long enough, the blood-sugar levels had returned to normal prior to discharge. Glycosuria of slight degree was found in 2 patients. In none of the patients with abnormalities in the tolerance for glucose was the presence of diabetes mellitus discovered by the history, and in none of those who recovered was it shown by subsequent observations of the glucose level. In 3 patients, the ability to handle the added glucose was unimpaired, although the blood-sugar level was elevated. In the other 5 patients, the blood glucose was elevated at the end of two hours following a test dose of 25 gm intravenously.

vascular failure was present, the values were approximately normal, being 2 milliequiv per liter in each case.

Abnormalities in the alpha amino nitrogen concentration of the plasma or serum. The standard deviation from the mean of random determinations of the alpha amino nitrogen shown in the literature and in our own data is ± 0.4 mg. The mean for normal values is 4.1 mg per 100 cc of plasma.^{9,10}

Although it is known that increases in alpha amino nitrogen occasionally occur in serum left in contact with cells,¹¹ determinations of this substance were made occasionally on serum as a matter of convenience. When this was done, the cells were removed as rapidly as possible and hemolysis was absent. For statistical purposes, no alpha amino nitrogen value was accepted as elevated that did not deviate from the mean by more than four times the standard deviation. In other words, it was accepted that the probability was only 1 in 1000 that an alpha amino nitrogen value above 6.0 mg per 100 cc of plasma or serum was due to chance alone. On this basis, 4 of the 10 patients with peripheral vascular failure had elevated alpha amino nitrogen values. These patients (Cases 3, 5, 7 and 12) had marked (+++) or extremely marked (+++++) peripheral vascular failure.

At the same time it should be noted that the patients in Cases 3, 5 and 12 showed evidence of liver damage, as indicated by an increased prothrombin time and an elevated icterus index. Furthermore, the patient in Case 12 showed unmistakable evidence of cirrhosis of the liver at autopsy, and the patient in Cases 5 and 7 gave evidence of acute liver damage on histologic examination. The patient in Case 3 showed clinical evidence of previous liver damage. The great majority of patients with more than moderate (++) peripheral vascular failure, however, showed an increase in either the icterus index

Case 9, cyanosis and peripheral vascular failure were present but both the arterial and venous saturations were normal, which suggested that the circulating blood was a poor index of the anoxic state of the obviously cyanotic and probably anoxic tissue.

Studies of the Biochemical Abnormalities in Certain Cases

Typical cases from the group of patients with infection or various cardiovascular conditions and

TABLE 2 Clinical Data on Patients with Severe Medical Illnesses

CASE No	TYPE OF ILLNESS	AGE	SEX	DEGREE OF PERIPHERAL VASCULAR FAILURE	FATAL OUTCOME
Infection					
Pneumonia					
2	Pneumococcal (Type 7)	57	M	+	Recovered
9	Pneumococcal (Types 3 and 14)	62	F	+	Recovered
8	Streptococcal	19	M	0	Recovered
6	Undetermined	71	M	++	Died (not in peripheral vascular failure)
4	Meningitis (Type 14 pneumococcus)	60	F	++++	Died in peripheral vascular failure
5	Pericarditis (Type 1 pneumococcus)	68	M	++++	Died (not in peripheral vascular failure)
Cardiovascular disease					
1	Myocardial infarction with heart block	72	F	+	Recovered
7	Dissecting aneurysm	60	M	++++	Died in peripheral vascular failure
12	Mesenteric thrombosis	30	M	+++	Died in peripheral vascular failure
Poisoning					
10	Barbiturate (I)	32	M	0	Died (not in peripheral vascular failure)
11	Barbiturate (I)	30	F	++++	Died in peripheral vascular failure
3	Gastrointestinal hemorrhage	54	F	+++	Died in peripheral vascular failure

or the prothrombin time, or both, without any significant increase in the plasma alpha amino nitrogen.

Blood oxygen and arteriovenous oxygen differences (femoral). There is no evidence from the data in Table 3 that there is any degree of correlation between the oxygen content or saturation of the arterial or venous blood and the degree of peripheral vascular failure. Five patients with marked (++++) or extremely marked (+++++) peripheral vascular failure, however, showed an arterial oxygen saturation of 85 per cent or less, 100 per cent hemoglobin being considered equivalent to 20.9 vol of oxygen per 100 cc of blood. The patient in Case 3 had a marked anemia from blood loss, as well as a marked unsaturation of the remaining hemoglobin. In all other cases, the patients had either a normal or a somewhat elevated hemoglobin concentration. The elevation of the hemoglobin did not show a great deal of hemoconcentration in relation to the severity of the peripheral vascular failure. Indeed, the patient in Case 10, who had no peripheral vascular failure, had the highest hemoglobin concentration — 117 per cent. The patients in Cases 9 and 10 had low arteriovenous oxygen differences. In

a case of probable barbiturate poisoning will be presented. Each of these patients had at least marked (++++) peripheral vascular failure in association with the severe illness.

CASE 5 A 68-year-old man with pericarditis (pneumococcal, Type 1), peripheral vascular failure estimated at ++++

This patient had been suffering from a vague illness associated with epigastric pain and constipation of 10 days' duration. He was seen by his physician on the day previous to admission, at which time the pulse, temperature, heart and lungs were reported to be normal. Shortly before admission he became extremely dyspneic and mentally confused. Examination on admission revealed a well developed and well nourished elderly man suffering from marked respiratory distress. The blood pressure was unobtainable. The femoral pulse was 180, the respirations 40, and the rectal temperature 97°F. The patient was mentally confused, irrational and apprehensive. The skin was cold and dry, with mottled cyanosis of the extremities as well as of the lips and nail beds. Examination of the lungs revealed medium moist rales throughout both lung fields. On percussion the heart was 13 cm to the left and 4 cm to the right of the midsternal line. The sounds were distant and muffled, without murmurs or friction rubs. The radial pulse was not palpable, but the femoral pulse was obtainable and was markedly paradoxical. A clinical diagnosis of pericardial effusion was made, which was consistent with the electrocardiographic tracings. The patient was accepted for biochemical study and was classified as having ++++ peripheral vascular failure. During the period of unobtainable blood pressure, marked

biochemical abnormalities were observed (Figs 1 and 2). The blood glucose was markedly elevated (143 mg per 100 cc). The serum lactic acid was 14.6 milliequiv per liter, and the carbon dioxide content of the serum was reduced to 8 millimols per liter. The serum nonprotein nitrogen was elevated to 276 mg per 100 cc, and the alpha amino nitrogen was at the extremely high level of 20.0 mg. The arterial

of purulent fluid was removed from the pericardium. A catheter was inserted into the pericardium and used for irrigation with penicillin. Immediately after the first pericardial tap, the blood pressure rose to 70/50 and there was marked relief of respiratory distress. The second blood sample was obtained 7 hours after the first and 5 hours after the pericardial tap. At that

*Glucose administered parenterally

oxygen content was 14.0 vol per cent, which in the presence of a hemoglobin concentration of 84 per cent indicated a saturation of 79 per cent. The Quick prothrombin time of the initial blood was prolonged to 35 seconds (normal, 21 seconds). The icterus index was 12.5.

Shortly after the initial blood was taken, a pericardial tap was performed and 150 cc of yellowish-green purulent

fluid was removed from the pericardium. A catheter was inserted into the pericardium and used for irrigation with penicillin. Immediately after the first pericardial tap, the blood pressure rose to 70/50 and there was marked relief of respiratory distress. The second blood sample was obtained 7 hours after the first and 5 hours after the pericardial tap. At that

time there was no evidence of peripheral vascular failure, nor did it later recur. The blood glucose on this sample had risen to 172 mg per 100 cc. In subsequent samples it fluctuated between 155 and 225 mg until the 3rd hospital day. A glucose-tolerance test was made from the 4th to the 6th hour after the initial blood was taken. It was grossly abnormal. Unfortunately, the blood glucose was at a high

FIGURE 1

fluid was removed. This fluid and a simultaneous blood culture showed the presence of Type 1 pneumococcus. Twenty-five thousand units of penicillin in 25 cc of saline solution was instilled in the pericardium by a second tap. A pericardial exploration was made, at which time a further 200 cc

level at that time and continued to rise during the subsequent 5 hours. The interpretation of the finding is therefore extremely difficult.

A sample of heart blood taken just prior to death on the 4th day gave a low level of glucose (39 mg per 100 cc). The

serum lactic acid level fell promptly after return of the blood pressure to relatively normal levels, falling from the initial level of 14.6 to 4.0 millimoles per liter. Subsequent levels taken at varying intervals of time until death gave values of 3.2 and 3.6 milliequivalents.

The carbon dioxide content rose rapidly from the initial level of 8 millimoles per liter to 24.5 millimoles as peripheral

the patient remained mentally confused, with a uremic odor on the breath and a uremic frost on the face, until death.

Autopsy. The kidneys were grossly normal. They stripped easily and were of average size and weight. Histologically there were no essential abnormalities except acute edema and congestion. The liver microscopically revealed marked central necrosis, but it was thought that the morphologic

†Normal 21 to 26 seconds

vascular failure subsided, and remained at these normal levels for the 24 hours over which observations were made. There was no important statistical change in the oxygen content, although the oxygen saturation rose to 91 per cent after the operation but in 24 hours had fallen to 75 per cent of saturation.

The nonprotein nitrogen remained above 200 mg per 100 cc. until death, but the serum alpha amino nitrogen fell

findings were consistent with an acute rather than a chronic change.

CASE 7. A 60-year-old man with dissecting aneurysm of the aorta, peripheral vascular failure estimated at ++++

Three hours before admission the patient developed a dull, aching pain at the anterior base of the neck, without radiation. Shortly afterward he experienced a dull, aching, "smother-

*Glucose administered parenterally

oxygen content was 14.0 vol per cent, which in the presence of a hemoglobin concentration of 84 per cent indicated a saturation of 79 per cent The Quick prothrombin time of the initial blood was prolonged to 35 seconds (normal, 21 seconds) The icterus index was 12.5 Shortly after the initial blood was taken, a pericardial tap was performed and 150 cc of yellowish-green purulent

time there was no evidence of peripheral vascular failure, nor did it later recur The blood glucose on this sample had risen to 172 mg per 100 cc In subsequent samples it fluctuated between 155 and 225 mg until the 3rd hospital day A glucose-tolerance test was made from the 4th to the 6th hour after the initial blood was taken It was grossly abnormal Unfortunately, the blood glucose was at a high

FIGURE 1

fluid was removed This fluid and a simultaneous blood culture showed the presence of Type 1 pneumococcus Twenty-five thousand units of penicillin in 25 cc of saline solution was instilled in the pericardium by a second tap A pericardial exploration was made, at which time a further 200 cc

level at that time and continued to rise during the subsequent 5 hours The interpretation of the finding is therefore extremely difficult A sample of heart blood taken just prior to death on the 4th day gave a low level of glucose (39 mg per 100 cc) The

were suggestive of anterior infarction, with probable septal involvement. Signs of peripheral vascular failure became evident, and the patient was transferred for study. The blood pressure had fallen from 138/98 to 80/50. The extremities were cold, and there was marked peripheral vasoconstriction. One hour later, the first biochemical studies were made, the blood pressure at that time being 90/70 and varying between this level and 80/50 for the next 6 hours, at which time the second blood samples were collected.

Twenty-four hours after the initial blood was taken, the signs of complete heart block cleared and the blood pressure rose to 100/60. Signs of peripheral vascular failure disappeared. The patient gradually improved and was discharged 9 weeks after entry.

The blood sugar on the initial blood was elevated to 195 mg per 100 cc. and remained above 150 mg for the first 6 days (Fig. 3). Following this, the blood-glucose level gradually declined, and on the 24th hospital day it was normal.

The prothrombin time and the icterus index remained normal throughout the hospital stay. With the exception of the blood-glucose level, the biochemical abnormalities referable to carbohydrate metabolism were minimal.

Two of the 12 patients studied (Cases 8 and 10) showed no evidence of peripheral vascular failure. Case 10 was one of probable barbiturate poisoning, and the patient died 12 hours after admission. A complete blood study was made seven and a half hours prior to death. A glucose-tolerance test showed an abnormal tolerance. This was the only biochemical abnormality observed. An interesting phenomenon was the presence of marked fibrinolysis in the blood five and a half hours prior to death.

FIGURE 3

Glucose-tolerance tests were slightly abnormal during the period when hyperglycemia was present. A glucose-tolerance test after discharge was normal, and the fasting blood sugar had been within normal range from the 19th day. Studies of this patient were discontinued on the 24th day.

The plasma lactic acid was 4 milliequiv per liter on the initial sample, rising to 6 milliequiv in 6 hours. Thereafter it declined, and at the time of the last sample, 70 hours after the study had commenced, it had reached a level of 2.5 milliequiv. The carbon dioxide combining power remained within normal limits throughout the study.

The nonprotein nitrogen was elevated to 80 mg per 100 cc on the initial blood plasma sample and rose to 135 mg 47 hours later. Seven days later, it had reached a level of 173 mg, and thereafter it slowly declined, reaching 58 mg on the 24th day after admission. The alpha amino nitrogen showed no statistically significant increase. The urine output during the first 2 days was small but not measured. It was 650 cc on the 3rd day and gradually increased to normal volume by the 5th day. Single urine specimens had specific gravities ranging from 1.002 to 1.012 during the first 8 days following admission. The sediment showed many white cells and occasional red cells and epithelial cells but no casts.

This blood sample was collected during a period of apnea, which terminated following the administration of oxygen and picrotoxin. The icterus indices of the patients in Cases 8 and 10 were normal, and the prothrombin time in Case 8 was normal.

The patients not described in detail follow similar patterns of response to those outlined above. The clinical manifestations in each case varied considerably, but the biochemical findings differed only in degree.

DISCUSSION

At the outset of this discussion, it must be emphasized that the clinical evaluations were arrived at without reference to the biochemical findings. In the final analysis, the data were arranged according to biochemical findings and the clinical interpreta-

single attack of "angina" 15 years previously. A brother was known to have died of a "ruptured aorta."

Physical examination revealed a well developed, well nourished man complaining of moderate precordial and abdominal pain. The pulse was 110, the rectal temperature 97°F, the respirations 25, and the blood pressure 40/20. The extremities were cold, clammy and cyanotic, and a mottled blue discoloration was observed over the flanks. The lungs were clear, but breathing was slightly labored. There was slight venous distention in the neck. The heart was not enlarged, but the sounds were distant and indistinct. The radial pulse was not palpable. The abdomen was soft, but some periumbilical tenderness could be elicited on deep palpation. The electrocardiographic record showed sinoauricular tachycardia and a slightly abnormal ST segment, which was interpreted either as being due to the heart rate or as being consistent with the presence of myocardial disease. A diagnosis of dissecting aneurysm of the aorta was made.

Although the patient received 1500 cc of saline solution, 500 cc of plasma and coramine, caffeine, morphine and oxygen, he remained cyanotic, with no obtainable blood pressure after the 1st hour. Seven and a half hours after admission he became irrational, and 2 hours later he died.

Only one set of blood samples was obtained for analysis. These were collected immediately after admission, when the blood pressure was 40/20. Blood was obtained for glucose determinations alone on two occasions when the blood pressure was unobtainable. The blood sugar on the initial sample was 332 mg per 100 cc and increased during the next 3 hours to 446 mg. The blood lactic acid was at the high level of 15.7 milliequiv per liter of plasma. The carbon dioxide combining power was 17 millimols per liter. A glucose-tolerance test showed the initial blood glucose to be 446 mg, 2 hours after the injection of 25 gm of glucose it was 351 mg. During this period the patient also received 500 cc of therapeutic plasma containing not less than 20 gm of glucose. The nonprotein nitrogen was normal, but the plasma alpha amino nitrogen on the initial sample was elevated to 6.5 mg per 100 cc.

Prothrombin times were not obtained, and the icterus index was normal.

Autopsy The liver showed acute focal necrosis, and a dissecting aneurysm of the aorta was found.

CASE 11 A 30-year-old, unmarried woman with presumptive evidence of poisoning by a barbiturate, peripheral vascular failure estimated at ++++

The patient had been treated for 2 months prior to entry for a "nervous breakdown," but was in apparent good health the day before admission. During that night the patient was noticed to be breathing heavily. In the morning she was comatose and was brought to the hospital in this condition. The only sedative known to be in her possession was Nembutal.

The past history showed no evidence of diabetes, hypertension or kidney or liver disease. There was no history of trauma, habitual taking of drugs or organic disorder of the central nervous system.

On admission, the temperature was 100°F, the pulse 120, the respirations 26, and the blood pressure 80/60. The patient was comatose and could not be aroused. The breathing was labored, and the skin was cyanotic and cold. The patient's general appearance was described as moribund. Over the back and lower extremities there were numerous first-degree and second-degree burns covering less than 3 per cent of the total body surface, apparently due to the application of hot-water bottles while the patient was in a comatose state. She was treated with oxygen, coramine, caffeine and unknown amounts of picrotoxin. Intravenous fluids were given, together with therapeutic amounts of sulfadiazine. A lumbar puncture was performed. The spinal-fluid pressure was equivalent to 490 mm of water, the total protein was 30 mg per 100 cc, and there were 1 white cell and 30 red cells per cubic millimeter.

Thirty-three hours after admission, when the patient was still comatose, additional clinical findings were obtained. The blood pressure was unobtainable. The extremities were cold and cyanotic, although the patient had been receiving oxygen since admission. There were medium and coarse moist rales throughout the lung fields. Examination of the abdomen revealed moderate muscle spasticity and flexion of the legs on deep abdominal pressure. Neurologic examination revealed dilated pupils that reacted slowly to light.

Reflexes were absent with the exception of a gag response, which was inconsistently observed.

Lumbar puncture was repeated and showed a normal pressure. The fluid contained only a few red cells. The patient was catheterized, and 80 cc of urine was obtained during the next 8 hours. The patient died 41 hours after admission. A medicolegal post-mortem examination was performed.

The first blood sample was taken 33 hours after admission, when the blood pressure was unobtainable. The blood glucose was 369 mg per 100 cc and in 2¼ hours rose to 586 mg. So far as the records show, no glucose was administered after the study was started. Just before death, 8 hours after the initial blood was taken, a sample of heart blood showed a glucose level of 293 mg per 100 cc.

The serum lactic acid on the initial sample of blood was markedly elevated (11.8 milliequiv per liter), and the carbon dioxide content of the serum was reduced (15 millimols). The lactic acid level fell slowly, being 8.4 milliequiv 3 hours later and 7.2 milliequiv shortly before death. A further observation of the carbon dioxide content showed a slight fall (13 millimols per liter) 2 hours after the initial sample.

The nonprotein nitrogen was 66 mg per 100 cc on the initial sample and rose to 91 mg at the time of death. The alpha amino nitrogen remained within normal limits throughout the period of study. The total urine output during the 41 hours following admission was approximately 290 cc, and the specific gravity was 1.030.

The arterial oxygen saturation was 81 per cent on the initial sample of blood and had risen to 87 per cent 3 hours later. The icterus index was normal throughout the course. The prothrombin time was distinctly prolonged, being 46 and 54 seconds (normal 24 seconds).

Autopsy The post-mortem findings were superficial burns of the skin, submucosal hemorrhages of stomach and small intestine, bronchopneumonia (right) and acute central necrosis of the liver.

The foregoing cases represent severely ill patients in whom the component of peripheral vascular failure was extreme. The following case represents a severely ill patient in whom peripheral vascular failure was minimal (+).

CASE 1 A 72-year-old woman with myocardial infarction and complete heart block, peripheral vascular failure estimated at +

This patient was admitted 1 year previous to the present entry with a possible acute diverticulitis. At that time there was no evidence from either a clinical or a biochemical viewpoint of any abnormality in the carbohydrate metabolism. Two years before the present admission, there was a gradual onset of dyspnea, palpitation and ankle edema, which never reached severe proportions. Two months before admission, the patient had a 3-hour attack of substernal pain and a choking sensation, which did not recur until 3 days before admission. This attack followed exertion and disappeared at rest. On the evening of admission, a severe substernal pain which was described as crushing, occurred. It radiated to the right shoulder and down the right arm. The patient vomited twice and had chilly sensations, with perspiration. Her physician gave her an injection of an unknown therapeutic agent, and she was admitted to the hospital 4 hours later.

Physical examination revealed a moderately obese woman in obvious substernal distress. The pulse was 96, and the blood pressure 130/98. The patient was mentally clear but slightly drowsy. The skin was warm and dry. There was no evidence of increased venous pressure in the neck. The lungs were clear to percussion, with some dry inspiratory rales posteriorly at both bases. The apex impulse of the heart was heard at the midclavicular line, and there were no murmurs. The sounds were distant. There was some tenderness in the right upper quadrant of the abdomen. Minimal ankle edema was present. Electrocardiographic records showed changes suggestive of an active process involving the anterior heart surface.

On the following day, the patient developed a complete heart block. The electrocardiographic findings at that time were as follows: auricular rate, 103, ventricular rate, 32-36, with evidence of right bundle-branch block. These findings

changes of the liver at autopsy. At the present time the possibility of hepatic function conditioned by decreased hepatic blood flow due to peripheral vascular failure as a cause of the increased alpha amino nitrogen observed in this series cannot be ruled out. The extremely high plasma alpha amino nitrogen in Case 7 (20 mg per 100 cc) requires some comment. This patient during the hospital stay had a plasma nonprotein nitrogen greater than 200 mg per 100 cc. The alpha amino nitrogen of blood plasma is usually 5 per cent of the total nonprotein nitrogen. One might therefore expect in this case that with a normal distribution of the nonprotein constituents of the plasma there would be an increase in the alpha amino nitrogen. It should be noted, however, that following the disappearance of peripheral vascular failure the alpha amino nitrogen fell abruptly from 20 to 10 mg per 100 cc, at which level it remained until death, although there was no parallel fall in the nonprotein nitrogen.

Azotemia has been found in several of the patients studied. In 1 case it was a serious complication. We⁶ have commented previously and elsewhere¹⁷ on the fact that the azotemia found in certain traumatic conditions was due to two components — an increased production of nitrogen and an impaired kidney function. Otherwise we⁶ have found a temporary azotemia associated with an oliguria that disappears when the normal urine output is restored. In most cases the azotemia found in the present series was of the latter character. In Case 5, in which the nonprotein nitrogen was over 200 mg throughout the patient's hospital stay and the signs of uremia were severe and progressive, only a minimal kidney lesion was found macroscopically or microscopically at post-mortem examination. Minor kidney impairment was indicated by urinalysis. In this patient also there is therefore a possibility that the azotemia was in part extrarenal.

The findings in this small series of cases indicate that the biochemical abnormalities accompanying peripheral vascular failure in patients suffering from severe medical illnesses are similar to those found in various traumatic conditions, hemorrhage and anoxia. Although the primordial cause is not known, it is not improbable that when peripheral vascular failure occurs it does so in association with tissue anoxia. Under these circumstances, it is suggested that there is a marked increase in glycolysis and possibly gluconeogenesis resulting in hyperglycemia. The production of lactic acid in amounts greater than the liver can transform or greater than can be excreted results in a marked lactic acidemia. If there is a concomitant disturbance in hepatic function, as the present data indicate, the lactic acidemia may be still further enhanced. Usually, although alpha amino nitrogen is an intermediate in gluconeogenesis, the amount of alpha amino nitrogen formed is easily handled by the

normal liver. Alpha amino nitrogen levels in the blood do not ordinarily increase with increases in nitrogen turnover. If, however, as a result of the presence of peripheral vascular failure there is a marked increased protein catabolism, with a failure of deamination due to an impaired liver function, an increase in alpha amino nitrogen is not improbable.

It has been reported that patients with severe medical illnesses may suddenly develop "diabetes" or if previously diabetic may have an exacerbation of their disease.¹⁷ It is not improbable that if the component of peripheral vascular failure is present such observations may represent additional cases of the type of biochemical lesion reported here.

Cardiac infarction has been reported to be accompanied by abnormalities in carbohydrate metabolism of a transitory nature in nondiabetic individuals.¹⁸⁻²⁰ Eckerström¹⁸ definitely relates the occurrence of such abnormalities to the presence of shock.

SUMMARY

The biochemical changes associated with peripheral vascular failure accompanying severe, acute medical illnesses are described.

They consist of hyperglycemia, lactic acidemia and a fall in the bicarbonate reserve. The oxygen saturation of the peripheral blood is reduced. The alpha amino nitrogen of the blood plasma is often elevated. There is usually a lengthening of the prothrombin time, and an elevation of the icterus index.

There is a marked correlation between the degree of the peripheral vascular failure and the profoundness of the biochemical abnormality.

tions were added. Had the reverse procedure been carried out, — namely, an arrangement of the cases on the basis of the degree of involvement with peripheral vascular failure, — the biochemical data would have presented the same pattern as is set forth in this report. The choice of lactic acid levels as the basis for the biochemical arrangement of the data on abnormal carbohydrate metabolism was made because it was the only carbohydrate component that was in no wise directly altered by the necessary therapeutic procedures.

The method of grading the degree of peripheral vascular collapse is quite arbitrary. It is not offered as representing a desirable method, but simply indicates a justification for the classification of peripheral vascular failure used in this presentation. A much larger series of cases would be required to give it greater value. By its use, however, two clinicians were able independently to agree on the status of the clinical material. With the use of these criteria, the data show clearly that there is a high degree of correlation between the existence of peripheral vascular failure and the presence of marked abnormalities in the carbohydrate metabolism of human subjects. This is true regardless of the type of medical illness studied, of which the peripheral vascular failure is a component. Furthermore, on the basis of lactic acid determinations this small series of patients indicates a close parallel between the degree of peripheral vascular failure and the profoundness of abnormality.

In two cases in which peripheral vascular failure was absent, the disturbance of carbohydrate metabolism was minimal or absent. It is true that consideration must be given to other factors, such as the patient's age and the severity of the illness. The latter is difficult to evaluate, since no patient was studied who was not considered severely ill at the outset. The question of age is more pertinent, since it is known that abnormalities in carbohydrate metabolism occur oftener in the older age groups than in the younger ones. This is notably true in the case of diabetes mellitus.¹² The findings in the 2 cases of presumptive barbituric poisoning (Cases 10 and 11), however, offer some support to the belief that age is not the only determinant. These patients were both in the early thirties, and both had so severe an illness that they died. On the initial blood samples alone, however, the patient in Case 11 had marked disturbance in carbohydrate metabolism, as indicated by hyperglycemia, lactic acidemia and acidosis, whereas the patient in Case 10 showed no observable changes in these biochemical findings. The only significant difference between the two patients was that in Case 10 peripheral vascular failure was entirely absent, whereas in Case 11 it was severe and had been present for some length of time. The patient in Case 8, who was nineteen years old, also showed no peripheral vascular

failure and only minimal abnormalities in carbohydrate metabolism.

Although such abnormalities in the glucose-tolerance curves showed in the main an intolerance for glucose, many of the curves were not subject to interpretation owing to the rapid and spontaneous fluctuations in glucose at the time of observation. In any event, although abnormalities in glucose tolerance were of the diabetic type, there was no evidence of clinical diabetes in any patient. Furthermore, in the patients who recovered from their illnesses there was evidence of a return of the carbohydrate metabolism to normal. Further follow-up studies will be made and reported later.

Concerning the cause of the abnormality in carbohydrate metabolism, there is no evidence to be drawn from this report. In a previous report some of the most widely accepted theories were reviewed.⁶ One may speculate on one contributing factor in these patients. Hematocrit and protein data show that diminution of blood volume although sometimes present was never great and probably could not account for the degree of peripheral vascular failure found. Anoxia is known to produce such biochemical changes as are given here.^{13,14} In the production of such an anoxia a reduction in cardiac output may play an important role. On the basis of laboratory and clinical findings, at least three types of anoxia were obviously present in these patients — anoxic anoxia (Case 12), anemic anoxia (Case 3) and presumably stagnant anoxia in the cases with marked cyanosis.

It is of considerable practical importance that femoral venous oxygen determinations give no clue to the state of oxygenation in the tissues in the latter cases. This may well be due to the presence of arteriovenous shunts in the periphery, as first proposed by Cannon¹⁵ and recently postulated by Glenn and his associates.¹⁶ It is significant that oxygen content, saturation and femoral arteriovenous oxygen differences in the few patients studied failed to show a high degree of correlation with the degree of peripheral vascular failure.

That functional disturbances of the liver exist in patients with a marked degree of peripheral vascular failure is inescapable. High icterus indices or prolonged prothrombin times, or both, were present in all patients showing more than the mildest form of peripheral vascular failure, regardless of the disease from which the patient suffered. In some cases the existence of early central necrosis was found in the liver at autopsy.

The alpha amino nitrogen was raised to levels of statistical significance in Cases 3, 5, 7 and 12. In each case there was profound peripheral vascular failure, but in Cases 3, 5, and 12 there was also a strong indication of derangement of liver function. In Case 7, in which there was normal icterus index and no determination of prothrombin time was made, there was evidence of acute degenerative

been passed. Certain minimum standards of early diagnosis must be provided.

In the modern enthusiasm for radiologic diagnosis, the venogram has received ardent support from many students of venous diseases, among them Fine and Sears,¹⁶ Starr, Frank, and Fine,¹⁷ dos Santos,¹⁸ Bauer,¹⁹ Welch, Faxon, and McGahey,²⁰ DeBakey, Schroeder and Ochsner²¹ and Dougherty and Homans.²² On the other hand, there are many investigators who question the value of venography, these include Bancroft,¹⁰ deTakats,^{1, 23} and Allen, Linton and Donaldson.⁷ It is perhaps significant that some of the advocates of this type of examination in the past have become increasingly more critical in more recent years. Thus, Fine²⁴ in a recent article shows a considerable decrease of enthusiasm for the procedure. Homans²⁵ recently called venograms disappointing. Welch and Faxon¹² admit that cases occur in which clinical signs of venous occlusion precede the positive findings of the venogram.

The objections to venography offered by the workers opposed to its use are as follows. There is a definite risk of either initiating or increasing the venous thrombosis. The examination is usually moderately expensive and requires material and apparatus that are not always available. False-negative reports occur in as many as 33 per cent of cases and are especially frequent in the early stages of the disease, when phlebothrombosis is actually most dangerous. There is a large group of venograms in which the interpretation of findings is extremely difficult, especially those of the legs, in which physical signs are minimal — the very cases in which venograms would be most desirable if they were reliable. Lastly, venospasm is frequently impossible to differentiate from organic occlusion. It is probable that a paravertebral sympathetic novocain block preceding the venogram would remove this limitation.

In addition to these objections, there are normally present at least six deep veins of the lower extremity — the paired anterior tibials, the posterior tibials and the peroneal veins. Although venography has been a frequent procedure at this hospital, I have never seen a venogram, either pathologic or normal, in which it was possible to outline these six trunks. If the experience of other observers has been similar, this indicates the extremely limited value of venography in the diagnosis of early phlebothrombosis of the calf veins.

The almost universal acceptance of the sign described by Homans¹³ as one of value in diagnosing venous occlusion is subject to some question. Reasoning that this maneuver stimulates too many things at one time, I have had an interesting experience in the last year or so. I have tried this maneuver in 88 patients who had other pathologic conditions not related to phlebitis and in whom phlebothrombosis was not suspected, either at the

time of examination or later. This series included 4 patients with contusions of the calf, 6 with fractures of the tibia or fibula, 1 with osteogenic sarcoma of the tibia, 3 with osteomyelitis of the tibia, 2 with septic arthritis of the knee, 2 with septic arthritis of the ankle, 3 with myofasciitis of the calf muscles, 15 with recent ankle sprains, 2 with lacerations of the calf muscles, 1 with a recent penetrating wound of the calf, 4 with recent poliomyelitis, 6 with cellulitis of the subcutaneous tissue of the calf, 5 with various types of acute meningitis, 2 with ruptured intervertebral disks, 4 with "sciatica" of undetermined cause, 7 with peripheral neuritis, 6 with occlusion of the popliteal artery, 1 with scleroderma, 12 adolescents and young adults with ankle fractures whose casts had just been removed, 1 with hysteria and 1 with heat cramps. All these patients demonstrated both limitation of passive dorsiflexion of the ankle and pain in some portion of the calf on performance of this test. Furthermore, none of them subsequently developed emboli or any further local signs compatible with venous occlusion.

Evidence that the incidence of false-negative reactions is high is afforded by Allen's¹⁴ experience, in which only 59 of 202 patients showed Homans's sign in the early phases, although he considers the test as absolutely diagnostic when present — an opinion in which I cannot concur.

In view of the severe limitations of the venogram and the Homans test in the early phase of phlebothrombosis, and the further fact that the classic picture of this malady is actually the late one and is thus valueless in the incipient stage, the question of how one is to make the early diagnosis arises.

It has been noted at this hospital that tenderness of the posterior calf, either localized or extensive and following the course of the deep veins, is almost always the first local sign of venous thrombosis, as has been reported by Veal and Hussey.¹⁵ With the exception of the infrequent cases in which pulmonary embolus precedes local signs of any kind, the stage in which tenderness is the only sign is the ideal time to make the diagnosis and of course to perform a proximal ligation. We see great numbers of such patients owing to the daily examination of the calves of patients whose age, general condition and confinement to bed for long periods make them peculiarly liable to this complication.

Obviously, however, not every patient developing tenderness along the posterior calf has venous disease as the cause. If there were a method of knowing that the tenderness elicited was venous, the diagnosis at this stage would be greatly simplified. In actual practice, pressure along the posterior calf causing pain permits the same diagnostic fallacies as those encountered in the Homans test, because, again, many structures are being simultaneously compressed. The skin, subcutaneous tissue, fascia and large calf muscles are, however, capable of being tested as a group aside from the

THE EARLY DIAGNOSIS OF PHLEBOTHROMBOSIS*

WILLIAM R. MOSES, M D †

WASHINGTON, D C

NOTHING so captivates the medical mind as the prevention of catastrophe by a simple method. Thus may be explained the rapidly increasing popularity of proximal ligation of thrombosed veins for the prevention of pulmonary embolism. Indeed, there must be few surgeons who have not witnessed the shockingly sudden transition of a happy convalescent into a patient rapidly dying from this totally unexpected disaster. Nor is the picture of so-called "thromboembolism" infrequent. Neumann² in a study of 165 random cadavers, found that 65 per cent of them demonstrated ante-mortem venous thromboses of the lower leg, 52 per cent of which were bilateral. He also stated that 12 per cent of all these thromboses were associated with massive pulmonary embolism and that an additional 34 per cent were associated with multiple nonfatal emboli. Rössle³ reports that 11 per cent of routine autopsies of patients over twenty years of age showed thromboses of the femoral vein and that 30 per cent of these had developed massive pulmonary embolism. Hosoi⁴ attributes 1 death per 1000 hospital population to pulmonary embolus.

Pilcher⁵ assigns to embolus 1 death following every 1000 surgical operations. Henderson⁶ states that it is the cause of 6 per cent of all postoperative deaths. Allen,⁷ quoting Davis of the Massachusetts General Hospital, claims that 3 deaths from embolus followed every 1000 operations. Hunter and his associates⁸ attribute 3 per cent of all hospital deaths to pulmonary emboli, and find that 53 per cent of bedridden patients develop deep-vein thrombosis of the legs. McCartney,⁹ reviewing over 25,000 autopsies, found 2.7 per cent of the deaths to have been due to emboli in the lungs and estimated that 5.3 per cent of postoperative deaths resulted from this complication. Bancroft¹⁰ expects pulmonary embolism in 10 per cent of victims of phlebothrombosis. Miller and Rogers¹¹ encountered 7 deaths in 206 patients with clinically recognizable thrombophlebitis.

There thus remains little doubt of both the ubiquity and the seriousness of this condition. At the present time, although there are notable cham-

pions of the medical management of these non-inflammatory venous thrombi, the greatly preponderant opinion is that proximal ligation, with or without thrombectomy, provides the safest, surest, simplest and cheapest prophylaxis against pulmonary metastasis of the clot.

Regardless of the therapy preferred by the individual physician, however, the selection of cases for treatment rests primarily on the diagnosis of the presence of these thrombi. But establishment of the diagnosis is in itself not at all adequate, the diagnosis must be made at the *earliest possible moment* if the duties of the physician to the patient are to be fully discharged. Welch and Faxon¹² state the problem concisely by asserting that the importance of the diagnosis of deep phlebitis is exactly in reverse ratio to the ease with which it can be made. The surgeon who waits for the full-blown picture of phlebothrombosis, edema of the calf and foot, distended superficial veins, well developed tenderness of the calf and sole, cyanosis of the part, a positive Homans test,¹³ a low-grade fever, tachycardia and an increased sedimentation rate will have lost his greatest opportunity to prevent emboli. There of course remain certain patients in whom the first suspicion of venous disease is aroused by an episode of pulmonary embolus. This contingency has been mentioned by Bancroft,¹⁰ by Allen,¹⁴ who states that chest pain was the first sign in 41 per cent of 202 patients, and by Veal and Hussey,¹⁵ who found that in 10 of 84 patients an embolus was the first factor that drew attention to venous occlusion.

It seems reasonable, however, to predict that the incidence of such unexpected emboli will be substantially reduced by daily or twice-daily inspection of the calves and soles in cases in which the patient's age, the nature of the illness or operation and relative immobilization lead one to expect phlebothrombosis. The examination requires only a few minutes, thus imposing a small price for the prevention of the great majority of these tragedies.

It has been stated that the diagnosis must be made extremely early if the patient is to receive the fullest value of the available procedures. Accordingly, the clinical picture described above must be recognized as the advanced phase of the disease, a phase in which probably the greatest hazard has

*From the Surgical Service, Gallinger Municipal Hospital.

the stage in which the greatest risk of pulmonary metastases has passed

The limitations of venography in making the early diagnosis are discussed. Evidence is also presented that the other great standby, the Homans test, is fraught with certain unavoidable fallacies that result in a dangerously large number of false-positive and negative responses.

A clinical test for the differentiation of early phlebothrombosis and the lesions simulating it is described, and the results of its clinical trial are outlined.

THE REGIONAL INJECTION OF PENICILLIN IN LOCAL INFECTIONS

A Preliminary Report

DAVID ROSE, M.D.,* AND DAVID HURWITZ, M.D.†

BOSTON

THE advent of penicillin has opened up innumerable fields of exploration in the treatment of infection. Sufficient work has been done and enough reports have been published on the production, assaying and pharmacology of the drug to permit omission of their discussion. This report is mainly concerned with the administration and dosage of penicillin in local infections, with direct regional injection and without systemic injections or other local therapy.

There have been many attempts to use penicillin locally. Peck¹ reported 15 cases in which this drug was employed locally with good results. He, however, also used it systemically, and in some cases in combination with sulfonamides and local treatment consisting of x-ray and incision. The local use consisted of injection into the necrotic mass or a sinus and prevention of drainage by occlusion with adhesive tape. These treatments were often repeated every three hours, each dose consisting of 100 to 1000 units. Florey² recommended the use of penicillin locally. He found it best to establish a closed cavity when possible, into which penicillin could be instilled and from which exudate could if neces-

sary be sucked periodically. Cutler³ advocated penicillin mixed with dehydrated human plasma and applied with a powder insufflator. Sophian⁴ recommended an ointment containing penicillin for topical application for furunculosis and similar infections. Flippen⁵ states that penicillin may be injected into a localized abscess cavity after aspiration of pus. He warns against the spread of infection by the purely mechanical means of distending firm areas of cellulitis, which we have proved in our series to be an unnecessary cause for alarm. Poate⁶ advocates the use of penicillin in solution, introduced through a fine tube into wounds, and as a powder, which is sprayed. Fisher⁷ reported 95 cases treated by instillation and irrigation, in which the lesion was either open or well drained.

The present report is a preliminary one on the use of penicillin by direct injection into the infected tissues. This method is in contradistinction to so-called "injections" that are actually instillations into sinus tracts or cavities, the drug being retained by occlusion of the tract opening by adhesive tape or other means. In this series, the penicillin was injected hypodermically, the size and length of the needle varying with the type and size of lesion treated. The best results were obtained by injecting well outside the involved area and directing the

deep veins by a simple test. The test employed is as follows:

Firm pressure of the fingers is used to explore for tenderness in any area of the posterior calf (Fig. 1). When the level of tenderness has thus been deter-

FIGURE 1 The First Maneuver

This comprises a careful search for tenderness in the deep posterior calf by direct compression with the fingertips in the anteroposterior direction.

mined, the calf is firmly compressed from side to side, and the degree of tenderness is compared with that elicited in the first part of the test (Fig. 2). In the presence of bland venous thrombi, the skin, subcutaneous tissue, fascia and muscles show little, if

FIGURE 2 The Second Maneuver

The calf is firmly compressed between the fingers and the palm in a lateral direction. In early phlebothrombosis this lateral compression is painless or relatively so, as compared with the first maneuver. The great majority of lesions simulating incipient thrombosis are accompanied by considerable tenderness on lateral compression. The findings in a case of peripheral neuritis, however, may be similar to those in a case of phlebothrombosis; accordingly, a brief neurologic examination of the extremity is included as the third maneuver.

any, tenderness on firm compression, whereas direct pressure on the veins, as executed in the first maneuver, causes definite pain. On the other hand, the superficial tissues are extremely tender at the second test if the tenderness resides in their layers. These two stages do not, however, rule out tenderness of the deep calf nerves, such as is present in a peripheral neuritis. The third part of the test is therefore a brief neurologic examination, with a search for al-

terations of cutaneous sensation and an evaluation of position sense of the toes, the vibratory sense and the deep reflexes.

Thus, given a patient in whom tenderness in the calf, either localized or diffuse, is discovered, the suspicion of a deep-vein thrombosis must be entertained. If lateral compression of the belly of the calf at this level is painless or markedly less painful than direct posterior compression, a presumptive diagnosis of phlebothrombosis is indicated. If cutaneous sensation, position sense, vibratory sense and the deep reflexes are then found to be normal, the final diagnosis of phlebothrombosis is warranted.

This test was first used in 12 cases in which thrombi were proved by operative exploration to be present in the venous system of the lower extremity. In each patient the criteria outlined above were exactly satisfied. In 3 cases there was neither pain nor limitation of dorsiflexion on forced passive dorsiflexion of the foot (Homans test). In 2 of 5 patients tested the venogram showed no definite block in either the calf or femoral veins.

Following this experience, proximal venous ligations have been performed at various levels in 59 cases. In 31 of these, phlebothrombosis was diagnosed, the remainder of the ligations being performed for prophylactic purposes, usually in the contralateral legs. In all the 31 cases, in which venous occlusion was suspected, the test described above was positive. In 14 of these, a clot was demonstrated by opening the femoral vein or the iliac vein. Of the remaining 17 cases, there was roentgenologic demonstration of pulmonary emboli and infarctions in 12. Since 95 per cent of pulmonary emboli are known to arise in the leg veins, this is strong presumptive evidence of peripheral phlebothrombosis.

In addition to these cases, I have seen 65 other patients in whom incipient phlebothrombosis was suspected. None of these cases yielded the findings described above, and in none was there subsequent evidence of advancing thrombosis, such as emboli, leg edema, cyanosis, venous distention or progressing tenderness. Twenty-six patients, however, showed calf pain on forced dorsiflexion and 31 presented some degree of limitation of dorsiflexion.

SUMMARY

The high incidence of phlebothrombosis of the leg veins is reviewed, and the lethal potentialities of the condition are discussed.

Considerable stress is placed on the early diagnosis of bland venous thrombi so that methods of prevention of pulmonary embolus may be instituted before the occurrence of this dreaded complication. Detection of these thrombi at this stage requires abandonment of the present dependence on finding the classic picture of thrombophlebitis, because this syndrome represents the late phase of the disease,

of the needle and progressing toward the center of the infection. The injection was made deeply in the tissue, not merely subcutaneously, except in cases in which the infection was within the skin, such as furuncles. A sterile needle was used for each injection site.

On the following day the lesion was examined and again injected. The dosage and volume were determined in relation to the progress of abatement of infection, and this procedure was continued until infection was completely controlled. A dry dressing was applied and was changed as needed if any discharge was present.

RESULTS

This series comprised 2 cases of osteomyelitis of the finger, 6 of felon, 6 of carbuncle, 3 of perianal infections, 6 of cellulitis, with and without abscess, and 2 of furuncle. Table 1 shows the types of infection, complications, dosage and so forth.

A few cases are worthy of discussion as illustrating the treatment and the results obtained.

Osteomyelitis

CASE 1 L J, a 36-year-old housewife, was a known diabetic patient who had neglected her treatment for 2 years. Twelve days prior to admission, she sustained a puncture wound of the right middle finger. This became infected and was seen by a local physician, who treated it by hot soaks and later by a small incision on the palmar surface at the tip. The finger became progressively worse, and on February 6, 1945, the patient was admitted to the Cambridge Hospital by one of us (D H), who had originally treated her diabetes. He found the diabetes uncontrolled and undertook its management. The finger was incised under general anesthesia and the pus was evacuated. Sloughing down to the distal phalanx was found. Cultures revealed *Staphylococcus aureus*. X-ray examination revealed osteomyelitis. The systemic use of penicillin, 120,000 units every twenty-four hours in divided doses every three hours, was instituted. This dosage was increased to 150,000 units every twenty-four hours and maintained for 8 days. During that time, the finger became progressively worse. There was a dusky, bluish swelling of the entire finger, with severe, constant pain and moderate discharge of pus. On February 13, two injections of penicillin, each of 15,000 units in 1 cc of solution, were made at the base of the finger on the medial and lateral sides toward the tip of the finger. On the following day, the patient was free of pain for the first time and the color and swelling of the finger had markedly improved. The same dosage and volume were employed daily, with the injections made closer and closer to the tip of the finger, the last three being made directly into the localized area of osteomyelitis. On February 19, 6 days after the local injections, the finger was of normal size and color. Motion was free, there was no pain or tenderness, and the discharge of pus had ceased. X-ray films showed slight improvement in the osteomyelitis. The penicillin was stopped, and on February 24 the patient was discharged. The diabetes was practically controlled. Two weeks later the finger was healed. There was no sequestrum.

This was the first case of any sort in which direct injection of penicillin into a local infection was employed. A subsequent case (Case 2) was treated earlier and more vigorously without systemic penicillin, and as good a result was obtained as in Case 1.

Felons

Felons need no special discussion, since Table 1 is self-explanatory, but one case merits brief mention.

CASE 7 E R, a 34-year-old female, was referred with felons of both thumbs. The left thumb, which had been incised and drained 7 days previously, was still painful and swollen and was draining freely. The right thumb was acutely infected and was tender, reddened and swollen. Under intravenous Pentothal Sodium anesthesia both thumbs were cleansed and painted. One hundred thousand units of penicillin was dissolved in 2 cc of saline solution, and 1 cc was injected into the left thumb below the depth of the incision. The remainder of the solution, with a fresh needle, was injected into the right thumb at two puncture sites. On the following day, the right thumb was needled and drainage of pus was obtained. No further treatment was instituted, and both thumbs promptly healed.

Carbuncles

The carbuncles demonstrated a marked and even spectacular response to direct-injection therapy. None of these cases had incision or even separation of bridges between cavitations. In 1 (Case 9), the carbuncle had been incised and drained a week before the patient reached our hands. It is of interest that this patient received more treatments (seven) with a greater total dosage of penicillin (495,000 units) than did those whose carbuncles had not been incised. In all these cases there was spontaneous evacuation of pus and separation of slough within two to five days after the onset of treatment. In some cases in the early stages of treatment heat was applied in the form of poultices or moist dressings. Later the use of heat was abandoned. All the patients were ambulatory following the first treatment. Two cases deserve explanation.

CASE 10 H C, a 47-year-old, married woman, was admitted to the Cambridge Hospital on March 28, 1945, after having been seen at home in consultation. There was a carbuncle on the lateroanterior aspect of the neck, overlying the large vessels. Its dome was 7 cm in diameter, with multiple oozing sinus points. The base measured 15 cm in diameter and extended down to the clavicle. The skin was reddened and burnt, with a vesiculation, as a result of too vigorous heat therapy before a physician was called. The temperature on admission was 102.4°F, and the pulse 100. The white-cell count was 15,400 and a culture revealed *Staph. albus*. Four cubic centimeters of penicillin, 20,000 units per cubic centimeter, was injected, with four sites of injection. Fifteen minutes after treatment, the patient was able to move her head and felt much more comfortable. On the following day, the area of redness and edema was markedly decreased and only moderately tender. One cubic centimeter of solution containing 30,000 units of penicillin per cubic centimeter was injected at each of four sites, which approached the center of the carbuncle. On the 3rd day the same dosage was employed, and later that day the slough was lifted out *en masse*. No further treatment was given, and 2 days later the patient was discharged home with a practically dry wound. It was completely healed within 10 days.

In this case, the location, size and poor condition of the surrounding skin was such as to make extensive incision and drainage a risky procedure.

CASE 11 B M, a 43-year-old man with a carbuncle of the left temple, was being treated by penicillin systemically and heat locally when his case came to our attention. The blood sugar was 111 mg per 100 cc. A blood culture was negative, and a local culture was not obtained because there was no discharging pus but only multiple points heading up. On May 11, 1945, 40,000 units of penicillin was given intramuscularly in divided doses and on May 12, 120,000 units was given. Following this, local treatment was advised and 20,000 units of penicillin in 1 cc of solution was injected at each of four sites. On the following day, there was a soft,

needle toward the center of the infected site, and by outlining the injection zone not by the visible cellulitis but by the zone of tenderness to palpation. The latter is often 0.5 to 1.0 cm beyond the outermost margin of redness in apparently uninvolved tissue. The rationale of this approach lies in an attempt to augment and reinforce the barrier that the body tissues set up to localize the spread of infection. Injection outside of and through the natural barrier to the center of infection thus aids the body reaction not only in preventing spread of infection but also in combating the infected tissue. This is a highly important phase in the administration of penicillin for regional use. Direct injection into the infected mass, although of value, does not produce so rapid and truly spectacular results as does the method described above. In addition to outlining the zone of tenderness, we have divided the area into three or four sections for injection.

In this series, injections were given once daily and the dosage was worked out for each case by virtue of the type, location and extent of infection. No case received solutions containing less than 15,000 units per cubic centimeter, and some received those containing as much as 60,000 units per cubic centimeter. In relation to dosage, there are two factors for consideration — the total volume and the number of units per cubic centimeter. In the first few cases treated, we hesitantly used solutions containing 15,000 units per cubic centimeter and divided the amount injected into two to four parts, depending on the number of sites. As the work progressed, it was found that the concentration could be increased without untoward results. The volume, however, is definitely limited by the site of infection. For example, in cases of felon or paronychia it is difficult to use a large volume, on the other hand, in cases of carbuncles or cellulitis, where there is considerable fatty and areolar space tissue, large volume can be employed.

Several general observations were made. Injections in fingers and hands are painful. This is apparently due more to the volume injected than to the concentration, since high concentrations in small volume were not much more painful than larger but more dilute volumes. Novocain nerve block was tried with some patients, but they complained as much of the block as they did of the penicillin injection. In 1 case, nitrous oxide and oxygen anesthesia was used to permit a high concentration in a felon. Intravenous Pentothal Sodium was employed in a case of bilateral felon. In all cases, within one to four hours after the initial injection the affected part became almost completely free of pain and could be actively used, and palpable tenderness was minimal. In all cases, the area treated became reddened and later mildly cyanotic, the latter condition persisting long after the infection had cleared up. In most cases desquamation of the skin took place after healing,

but in some it occurred during the healing process. There was no toxic reaction, and no sloughing of tissues.

In many cases in which pus formation had become established, spontaneous evacuation occurred during or after the second treatment. In some cases the pus was completely absorbed without evacuation. This brings up the question of desirability of evacuation of pus by needling or even by incision. During the first few treatments it was thought desirable to maintain a closed system so that the penicillin would be kept in contact with the pathogens and tissues more completely and for a longer period of time. It was also found that in the cases with a collection of pus near the surface it spontaneously evacuated during an injection or shortly thereafter. In some cases the pus was evacuated by needle after the initial treatment. For these reasons, we have not employed incision and drainage, and the lesions have responded just as well to treatment without them. This may seem contrary to one of the basic rules of surgical treatment, namely that evacuation of an enclosed pus pocket is the only correct treatment. Although this has been true up to the present, it now appears possible not only to limit the infection but also to overcome it without deforming incisions and with a marked decrease in disability, pain and length of hospitalization. It must, however, be kept in mind that this treatment does not preclude surgery in some cases. Judgment must be exercised in deciding whether the process of healing may be hastened by evacuation of the pus rather than by absorption. In such a case, evacuation by incision or needling can be done, but only after treatment by injection has abated the acute process and complete localization has been attained. To date, there have been only a few cases in which evacuation was done by needling and only 1 in which it was done by incision, in several cases the lesion had been incised previous to admission to the hospital.

In practically all cases, the systemic use of penicillin or sulfonamide therapy was excluded and no x-ray or other local therapy was employed.

METHOD OF USE

Penicillin dissolved in saline solution was prepared in the usual manner, the amount of saline used depending on the type and size of lesion to be treated. In fingers and other areas where loose tissue precluded a large volume, 2 to 4 cc was used to dissolve 100,000 units of penicillin, thus giving a concentration of 50,000 to 25,000 units per cubic centimeter. The parts were cleansed with soap and water and painted with an aqueous solution or tincture of Zephyran, and zones of tenderness mapped out. Whenever possible, two to four sites of injection were chosen. In all cases, the injection was made by hypodermic needle, starting outside the zone of palpable tenderness, injecting slowly ahead

erythematous edema about the upper face, extending into the eye and cheek of the affected side. Because of this, the local treatment was omitted by the attending physician, and 100,000 units was given systemically. On the following day, there was spontaneous drainage and separation of slough, which was lifted out. There were no further treatments, and 5 days later the lesion was practically healed.

This was the only case in which a local reaction was observed.

Anal Infections

The only comment that can be made concerning the use of penicillin in anal infections, until a larger number of cases are studied, is that local therapy cleans abscesses preparatory to surgical removal of fistulas. In Case 14, the fistula healed completely internally and externally and no later surgery was necessary.

Cellulitis

Cellulitis, with or without abscess formation, responds favorably to this mode of therapy. In fact, regional injections are of the utmost importance in limiting and localizing the spread of infection. In our 6 cases, there were 3 that never progressed to abscess formation. One case drained spontaneously, in 1 the pus was evacuated by needling, and had a small superficial incision for drainage. All these infections became localized in one to three days after onset of treatment. One case stands out as an example.

CASE 20 J G, a 41-year-old man, sustained a minor laceration over the palmar surface of the proximal phalanx of the left middle finger. Twenty-four hours later, the finger was twice its normal size, reddened and painful. A physician advised hot soaks and 1 gm of sulfathiazole thrice daily. After 3 days, an attempt to reopen the laceration, which had closed over, was made, but no pus was obtained. The same treatment was continued for 2 weeks, during which time the hand became worse. At the end of 3 weeks, when we saw the hand, there was a hard, brawny cellulitis involving the entire middle finger and the proximal portions of the two adjacent fingers, with a softer edema of the entire dorsum and palm of the hand. The finger was cyanotic and in stiff extension. It was tender and the site of a throbbing pain. There was general malaise but no fever. An immediate injection of 100,000 units of penicillin in 2 cc. of solution was made. The sites elected were lateral and medial to the initial laceration, using 1 cc. for each site and directing the needle deeply to the palmar fascia. On the following day, the palmar surface of the hand was only slightly swollen. The palmar surface of the finger was swollen but soft and nontender and its color was nearer normal. Its dorsal surface was still cyanotic, swollen and tender. This time the injection, with the same dosage and the same concentration, was made from the medial and lateral surfaces toward the dorsum. On the following day, the entire finger was normal in color, although with a soft swelling. There was no pain or tenderness. The palm was free of swelling, but there was a slight amount of soft swelling of the dorsum of the hand. The patient stated that he had had the first night of complete freedom from pain since the onset of infection. The finger was still stiff and could not be flexed. Without further therapy other than hot soaks, all swelling disappeared. Although some inability to flex is still present, slow improvement has continued.

Furuncles

No comment is needed concerning furuncles, since these are relatively simple infections. They respond well. Usually one injection in the sur-

rounding zone or under the base of the lesion is sufficient for complete relief and healing.

* * *

Cultures of all lesions were made when pus was present. The organisms found were either *Staph aureus* or *Staph albus*, except for Case 14, which showed *Streptococcus haemolyticus*.

The results were extremely gratifying. No deforming surgery was done. Evacuation of pus, when formed, was usually obtained by spontaneous evacuation or needling. There were no cases of sloughing, tissue necrosis or dissemination of infection. The reduction of disability (Table 2) and

TABLE 2 Duration of Disability

rapidity of healing are in favorable contrast to the results of orthodox surgical treatment.

SUMMARY AND CONCLUSIONS

Penicillin employed by direct injection is of definite value in limiting and overcoming local infections.

Concentrations of penicillin as high as 60,000 units per cubic centimeter may be used without complications. One of the values of direct injection is the ability it gives to produce a high local concentration, which is impossible by systemic use of the drug.

Disability is reduced far below the point reached by any other means of treatment.

There is no deformity such as that frequently following radical surgical incision and drainage.

Pain is quickly relieved — in some cases within one hour, and always within thirty-six hours.

Surgical judgment must be exercised regarding the necessity and proper time for evacuation. Preferably, no evacuation should be performed until complete localization by injection therapy has been carried out, and then only minimal surgery is indicated. Most cases evacuate spontaneously during localization, with freedom from pain.

Injections are painful, and the degree of pain is in direct ratio to the density of tissue and the volume of injection.

Injections once daily are adequate, but they must be maintained until definite subsidence of infection is evident.

The fear of spreading the infection by this treatment has not been substantiated. In part, this is due to the fact that injections are started well outside the center of infection, thus reinforcing the barrier and aiding in localization.

TABLE I Summary of Data

CASE No	AGE yr	SEX	DIAGNOSIS	ASSOCIATED DISEASE	CONCENTRATION units/cc	VOLUME cc	FREQUENCY OF TREATMENT	TREATMENTS	TOTAL units	OTHER TREATMENT	RESULT
1	36	F	Osteomyelitis of finger	Diabetes	15,000	2	Once daily	7	210,000	Incision and drainage on admission, 125,000 units of penicillin systemically for 10 days, without results treatment of diabetes	Complete healing, no sequestrum.
2	40	F	Osteomyelitis of finger	None	30,000	2	Once daily	7	420,000	Incision and drainage 2 weeks before treatment	Complete healing no sequestrum
3	18	F	Felon of finger	None	30,000	1	—	1	30,000	None	Absorption, no drainage.
4	19	F	Felon of finger	None	20,000	1	Once daily	3	60,000	None	Absorption no drainage.
5	21	F	Felon of finger	None	40,000 20,000	2 1	Once daily Once daily	1 1	100,000	Pus evacuated by needle day after first treatment	Complete healing
6	21	F	Felon of finger	None	40,000	2	Once daily	3	240,000	Needling 2nd day, no pus obtained	Complete healing; spontaneous drainage 3rd day
7	34	F	Felon of left thumb	None	50,000	1	—	1	50,000	Incision 7 days before admission	All drainage ceased after treatment, healed
			Felon of right thumb	None	50,000	1	—	1	50,000	Needled day after treatment	Complete healing; drainage of pus following needling.
8	47	M	Carbuncle of neck	None	30,000	3	Once daily	5	450,000	None	Spontaneous sloughing complete healing
9	60	F	Carbuncle of neck	None	15,000 30,000	3 3	Once daily Once daily	3 4	495,000	Incision and drainage before admission	Drainage and absorption complete healing
10	47	F	Carbuncle of neck	None	20,000 30,000	4 2	— Once daily	1 2	200,000	None	Slough lifted out en masse after third treatment complete healing
11	43	M	Carbuncle of left temple	None	20,000	4	—	1	80,000	Systemic penicillin 40,000 and 120,000 units before local treatment, and 100,000 units after local treatment.	Following local treatment, edema and erythema extending into eye and cheek, next day, spontaneous evacuation of slough, with rapid recovery
12	48	M	Carbuncle of neck	None	40,000 25,000	2½ 4	— —	1 1	200,000	60,000 units of penicillin systemically	Spontaneous evacuation 2nd day after treatment, complete healing
13	40	M	Carbuncle of left shoulder	None	40,000 45,000	2½ 4	— Once daily	1 4	820,000	None	Slough partially removed 2nd day, completely removed 5th day complete healing
14	13	F	Perianal abscess	Fistula and diabetes	20,000 40,000 20,000	5 3 5	Once daily Once every 5 days Once every 3 days	7 3 2	1,260,000	Treatment of diabetes	Complete healing of tract internally and externally
15	42	M	Perianal abscess (anterior)	Anterior fistula	10,000	4	Once daily	3	120,000	None	Spontaneous evacuation and healing of abscess
16	36	M	Draining perianal abscess (posterior)	Posterior fistula	12,500	2	—	1	25,000	None	Abscess dry 2 days after treatment
17	29	F	Cellulitis of palm	None	10,000	2	—	1	20,000	None	Absorbed completely, no drainage.
18	29	F	Cellulitis of base of thumb	None	10,000	2	Once daily	4	80,000	None	Absorbed no drainage.
19	21	M	Cellulitis of right knee (foreign body)	Diabetes	20,000	2	Once daily	3	120,000	None	Spontaneous drainage after first treatment
20	41	M	Cellulitis of left middle finger, with tenosynovitis	None	50,000	2	Once daily	2	200,000	Sulfonamide treatment for 2½ weeks before admission	Complete absorption residual stuff finger
21	26	M	Cellulitis with palmar abscess	None	20,000	2	Once daily	2	80,000	Needled for evacuation of pus	Complete healing
22	41	M	Cellulitis with palmar abscess	None	50,000	2	Once daily	3	300,000	Increased for evacuation of pus on 3rd day	Rapid healing
23	18	F	Furuncle of neck	None	20,000	1	—	1	20,000	None	Spontaneous drainage day after treatment
24	18	F	Furuncle of neck	None	40,000	1	—	1	40,000	None	Spontaneous drainage no day of treatment

erythematous edema about the upper face, extending into the eye and cheek of the affected side. Because of this, the local treatment was omitted by the attending physician, and 100,000 units was given systemically. On the following day, there was spontaneous drainage and separation of slough, which was lifted out. There were no further treatments, and 5 days later the lesion was practically healed.

This was the only case in which a local reaction was observed.

Anal Infections

The only comment that can be made concerning the use of penicillin in anal infections, until a larger number of cases are studied, is that local therapy cleans abscesses preparatory to surgical removal of fistulas. In Case 14, the fistula healed completely internally and externally and no later surgery was necessary.

Cellulitis

Cellulitis, with or without abscess formation, responds favorably to this mode of therapy. In fact, regional injections are of the utmost importance in limiting and localizing the spread of infection. In our 6 cases, there were 3 that never progressed to abscess formation. One case drained spontaneously, in 1 the pus was evacuated by needling, and had a small superficial incision for drainage. All these infections became localized in one to three days after onset of treatment. One case stands out as an example.

CASE 20 J G, a 41-year-old man, sustained a minor laceration over the palmar surface of the proximal phalanx of the left middle finger. Twenty-four hours later, the finger was twice its normal size, reddened and painful. A physician advised hot soaks and 1 gm of sulfathiazole thrice daily. After 3 days, an attempt to reopen the laceration, which had closed over, was made, but no pus was obtained. The same treatment was continued for 2 weeks, during which time the hand became worse. At the end of 3 weeks, when we saw the hand, there was a hard, brawny cellulitis involving the entire middle finger and the proximal portions of the two adjacent fingers, with a softer edema of the entire dorsum and palm of the hand. The finger was cyanotic and in stiff extension. It was tender and the site of a throbbing pain. There was general malaise but no fever. An immediate injection of 100,000 units of penicillin in 2 cc of solution was made. The sites elected were lateral and medial to the initial laceration, using 1 cc. for each site and directing the needle deeply to the palmar fascia. On the following day, the palmar surface of the hand was only slightly swollen. The palmar surface of the finger was swollen but soft and nontender and its color was nearer normal. Its dorsal surface was still cyanotic, swollen and tender. This time the injection, with the same dosage and the same concentration, was made from the medial and lateral surfaces toward the dorsum. On the following day, the entire finger was normal in color, although with a soft swelling. There was no pain or tenderness. The palm was free of swelling, but there was a slight amount of soft swelling of the dorsum of the hand. The patient stated that he had had the first night of complete freedom from pain since the onset of infection. The finger was still stiff and could not be flexed. Without further therapy other than hot soaks, all swelling disappeared. Although some inability to flex is still present, slow improvement has continued.

Furuncles

No comment is needed concerning furuncles, since these are relatively simple infections. They respond well. Usually one injection in the sur-

rounding zone or under the base of the lesion is sufficient for complete relief and healing.

* * *

Cultures of all lesions were made when pus was present. The organisms found were either *Staph aureus* or *Staph albus*, except for Case 14, which showed *Streptococcus haemolyticus*.

SYMPOSIUM ON MEDICAL SOCIOLOGY

PRACTICAL CONSIDERATIONS IN THE PLANNING AND CONDUCT OF A NATIONAL MEDICAL-CARE PROGRAM*

EDWARD S ROGERS, M D †

DURING the course of the preceding few weeks you have had laid before you an exceptionally well chosen review of facts, attitudes and plans with respect to the problem of medicine and its place in a changing social structure Regardless of the details of the views that you have formulated, there probably are few, if any, of you who will not agree that fundamental changes are in motion

Medicine as a science has been through, and is still in, a most amazing period of progress We need not review the evidence here Similarly, other forces of great moment to the social structure have been through periods of growth Transportation provides a good example Its growth and its new horizons have had far-reaching effects on our way of living It seems just as fallacious to adhere to the concept that the advances in medicine will not have their counterpart in changes in the former patterns of medical practice — our manner of living with respect to the use and distribution of medical services — as it would be to claim that modern transport has not brought and will not continue to bring changes in the country's standards and manner of living

These changes are not "around the corner" They are here today and will be even more so tomorrow Let anyone who doubts this but take the trouble to review the major party programs in the last presidential campaign Advances in social security, you will recall, were not an issue challenged by either, and medical care is recognized as an important part of social security

Regardless of the justifiable pride that we all enjoy in the past achievements of the medical profession, regardless of the high quality of the national health and regardless of the apprehensions that beset many in our ranks and make them shut their eyes, the facts in proof of the imperfections of the

present system of medical services are clear I therefore believe that change is not to be feared but rather to be sought

The facts have been ably pointed out to you in previous lectures, and you know them as facts, but how deeply do you feel them? Some of you may have experienced them at first hand, most of you probably have not You do not see people seriously lacking for medical facilities here The social implications of failures in preventive practice are not readily observed in the laboratory, the clinic or the classroom, although they are of course basic and are in the background You are not exposed to poor medicine in the cloisters of this school, and you are not being prepared to practice it But neither the world nor the Nation begins and ends in Boston with both feet in these buildings, as I used to think

I have sat in the seats you occupy, and, like you, I have been inspired, and I have also been put to sleep I am not stirred by any unusual sense of school patriotism, but I have always been proud to have graduated from these halls, because to have done so has numbered me, as it will you, among men well trained and with a high tradition, from among whom many of the leaders of this profession have risen Never before has the medical profession stood in greater need of sane, clear-thinking leadership, both now and in the years immediately before us, and these years will be the years of your increasing responsibility That is why I say that you know these facts but question how deeply you feel them

I have said that the need is great and that you will have much to do in determining the future I shall attempt to show you why

In the light of your studies and discussions, probably each of you has either formulated or is formulating your own plan, your own concept of the solution of the problem of medical care The many and various patterns of such concepts will reflect a variety of molding forces, such as your awareness of need, your experience, your type of information and interest, your intellectual methods and, by no means the least, your basic prejudices Yes, you

*This is the ninth and concluding of a series of nine lectures on medical sociology given weekly at Harvard Medical School during January, February and March 1945 they were sponsored by the Department of Preventive Medicine and were primarily intended for third-year students These articles have temporarily replaced the reports "Medical Progress"

†Assistant commissioner for medical administration, New York State Department of Health assistant professor of medicine Albany Medical College.

have them, — all of you, — and you have the most in all probability, when you fail to recognize them

In these respects you do not differ greatly from those in whose hands the delicate buds of the future of medicine lie today. To be sure, most of these men have had from a few to many years of experience, and some of them, thank heaven, are real leaders, rich in their ability to evaluate the forces in their own thinking and to recognize the merit in another's point of view. Many, however, are not so. They have had what should be rich experience, but they take a sort of polaroid point of view toward it and see only the things that are in parallel with their prejudices.

I have mentioned the formulation of a plan. This is essential if we wish to end our present more or less haphazard practices and move effectively toward an objective. I shall, however, be but little concerned with other than the broadest aspects of planning today, because what I have to say will apply equally to any plan. It is essentially this: your plan, my plan, the Surgeon General's plan or the President's plan will be no better than its chances of actually accomplishing its objectives.

Plans that purport to answer one phase or another of the problem of medical care are of frequent occurrence these days, and there are about as many variations as there are groups contributing them. Many of these plans have been in operation over a period of years. Especially is this true in other countries. By and large, however, with the exception of Russia, these programs, like those in operation in this country, fall short either of being comprehensive or of covering the entire population. And, as Dr Goldmann¹ doubtless advised you in his lecture, one must be circumspect in the matter of applying the experiences of other nations, with political and social structures so different from ours, as a pattern for our actions.

In this country one finds rapidly growing movements such as hospital insurance under Blue Cross systems, a large variety of voluntary medical and medical-indemnity insurance schemes for the low-income and certain industrial groups and a small but increasing number of fairly comprehensive hospitalization and medical-care plans for the indigent. But none of them, so far as I am aware, embrace comprehensive provisions for health and preventive services and for the improvement of the quality and distribution of medical services for other than limited segments of the population. Nor have they been developed as a part of a planned master strategy that envisions the way they fit into a total program of medical care.

Even in the area of national planning, it seems to me that there has been either too much opportunism or too little regard for sound basic principles, as in the Wagner-Murray-Dingell Bill of 1944. The hospital-construction bill (S-191) of Senators Hill and Burton, now before Congress, impresses

me as being much more realistic, and although it is not comprehensive in the terms of the whole problem, it nevertheless suggests that its authors have a pretty clear concept of how it would fit as a part of a rational master plan.

Among the comprehensive programs recommended by national organizations, that of the American Public Health Association² merits attention because it is clear, comprehensive and comparatively simple. Although it achieves this clarity and simplicity by the expedient of confining itself to a statement of a few objectives and principles applicable to method, it does so, of course, at the cost of begging a great many major problems of detail in technic. I am rather of the opinion that this is wise in national planning at this stage, but from the practical point of view of a person who wants to know exactly what he should do as a physician or an administrator, it is not of much help. We must start somewhere, however, and we must have some common ground of agreement regarding where we want to go. Such a common ground, when clearly stated and properly implemented with principles for our guidance, constitutes a master plan in the sense that I am using the term. Not to have such a plan would be analogous to trying to fight the present war without a master strategy. Yet the present lack of basic master planning and agreement in the war on the medical and health needs of the country is of this order.

You cannot escape your present and increasing responsibility and concern in this problem. You cannot evade it today as citizens. You should not evade it tomorrow as physicians. And some of you, I hope, will assume roles of leadership with respect to it in the years that lie ahead. It is not a problem that will be solved with the mere passage of a bill or two.

Accordingly, I want to discuss with you certain points of view and problems that may serve as guides to your thinking in relation to your responsibilities as citizens, physicians and potential leaders among physicians.

First of all, you should establish a set of values with which to measure this business of planning, and second, you ought to attain some insight concerning the practical problems of accomplishing a plan once it is accepted.

What are the fundamentals of a master plan? I can speak only for myself, of course, but to me it seems that such a plan should embrace the following characteristics. It must be clear as to its objectives, and these must be comprehensive in nature. It must be practical and make provision for the logical steps by which it is to be developed. It must meet the needs of and be acceptable to those whom it most greatly affects. It must contain the substance for authority, responsibility and orderly administration. Lastly, it must be flexible with respect to local situations and future developments.

The foregoing principles, platitudinous-sounding and perhaps overly concise, have not been lightly written. In them I have endeavored to include those elements of a plan that will determine whether or not it is realistic and capable of accomplishment. It will be worth while to consider each of these principles in more detail, both as abstract principles and in the light of current experience.

The plan must be clear as to its objectives, and these must be comprehensive in nature. Although we have achieved no single statement of national objectives in a formal sense, we are not far from it, and we can almost check this off as finished. For example, very few people will take serious exception to the objectives for a national medical-care and health program set forth by the American Public Health Association² in December, 1944, which read as follows:

1 A national program for medical care should make available to the entire population all essential preventive, diagnostic and curative services.

2 Such a program should insure that the services provided be of the highest standard, and that they be rendered under conditions satisfactory both to the public and to the professions.

3 Such a program should include the constant evaluation of practices and the extension of scientific knowledge.

Compare these with the following seven principles recently announced by the Council on Medical Service of the American Medical Association³:

1 Continued expansion of the practice of medicine with full development of approved voluntary hospital, medical, indemnity, industrial and commercial insurance against the costs of medical care.

2 Development of public-health facilities for preventive medicine all over the country.

3 Development of adequate diagnostic facilities everywhere.

4 The use of the voluntary-insurance principle in caring for the indigent and medically indigent.

5 The development of hospital facilities where present facilities are used to the utmost and are still inadequate.

6 The use of federal funds to aid communities in public-health measures, care of the indigent and construction of necessary hospitals, when local communities are unable to finance the projects, but with the retention of local administration.

7 The creation of a unified federal Department of Health, with a secretary in the Cabinet as the head of the department, such secretary to be a qualified physician.

Although I prefer the form of the American Public Health Association's statement, which is natural, since I had a part in its formulation, there are quite a few points of similarity in these two sets of objectives. Of course, those of the American Medical Association are not statements of pure objective, being intermixed with recommendations for the voluntary-insurance principle and other matters of method that are questions of an extremely controversial nature, and by the inclusion of which the framers detract from the force and value of their position.

Returning to the broad topic of social objectives, there is expectation that the President will include in a revised bill of rights, which it is thought he will present to Congress in the near future, as one among

eight or so others, the right to adequate food, clothing, shelter and medical care.⁴

Thus we find evidence of growing acceptance of a new concept — Congress painting in the broadest terms the rights of man, the American Medical Association moving a considerable distance from its former reactionism to admit of similar objectives, but with reluctance to face the realities of their fulfillment, and the American Public Health Association directing its recommendations in a more or less intermediate path, recognizing the merit of the objective but at the same time aware of the difficulties besetting its accomplishment. These, of course, are not the only groups that have made recommendations based on prolonged study,⁵⁻¹¹ but in general these other proposals lie within the limits of the views of these two associations with respect to their objectives.

The plan must be practical and make provision for the logical steps by which it is to be developed. By and large, people who study and think about these things at all can be classed in one of four groups.

First, there are the *revolutionists*. I do not mean anarchists, but rather those who believe that mass social changes can be brought about by force of law. These are the persons who believe that the end justifies the means, and that where the processes of growth under our democratic system are slow, changes can be worked out in detail in advance in the minds of a few men and more or less set on the rest of their less informed fellowmen through the process of legislation and centralized administration.

Second, there are the *evolutionists*, the progressives, those who feel strongly the need of change or readjustment but admit the imperfections of the human mind in foreseeing the problems to be faced and in devising their solution other than by a process of trial and error. To this process they add a provision for a positive sort of force pushing things along. These persons like to think of progress as a step-by-step procedure at a reasonably accelerated rate.

Third, there is a group who might be called the *slow evolutionists*, a somewhat more timid folk, sometimes called conservatives. They are too rational and objective in their approach to deny the desirability of progress, yet they are too fearful, either because of their innate nature, because of misgivings or because of personal risks involved in change, to wish to encourage it openly.

Finally, there is a fourth group, who, at the risk of being hackneyed, I can only refer to as the "worry birds," which, as is well known, fly backward because they do not dare to face where they are going but always like to talk about where they have been. This group, in my opinion, is typified by those usually called the *reactionaries*, the ones who state that because we have made creditable progress no further advance is necessary.

No doubt you have already classified your friends

and acquaintances, possibly yourself, in one or the other of these categories. I should regard myself, — quite possibly fallaciously but in any event with much company — as being in the best group — that is, an evolutionist. I am distinctly dedicated to progress but by the very nature of my experience I possess the utmost respect for the problems that beset the path of such progress.

Each of you will inevitably evaluate plans on the basis of the classification in which you really fall, but I urge that by whatever standards you judge a plan, you consider it in the light of whether it provides practical solutions to the over-all needs as you see them and whether you see in it the structure for logical development.

The plan must meet the needs of and be acceptable to those whom it most greatly affects. Again, let me remind you that we are discussing planning in terms of the likelihood of its accomplishing its objectives. The plan must therefore be acceptable, first, since lawmaking is involved, to those who are delegated the responsibility for making laws, second, since technical skills are involved, to those most intimately concerned with the provisions for such skills — namely, the medical profession, hospital administrators and ancillary technical workers, and finally, since public support is essential, to the recipients of the service, who are the public.

Broadly speaking, lawmaking falls into several categories of origin. Legislative acts may arise from political expediency in which the legislators either negotiate among themselves for political advantage, frequently of a somewhat subtle nature, or such legislation is conceived and executed through executive or legislative planning independent of actually crystallized public opinion, often as a result of the demands of pressure groups operating as well organized minorities and in self-interest. On the other hand, legislation may arise from the "grass roots," either spontaneously or as a result of leadership functioning within the structure of the truly democratic system and involving the long and arduous road of public education to a point of public recognition and action in behalf of its own best interests.

It is worth taking a few minutes to comment on the influence of pressure groups in the medical field, because this will throw some light on legislative processes and give further emphasis to the need that has been mentioned of a much more vigorous sense of public responsibility on the part of the medical profession. Two examples in my recent experience may serve as illustrations.

The first, although it represents an abortive attempt of a pressure group, is one of serious proportions and may eventually succeed. In the State of New York there are approximately 25,000 licensed doctors of medicine and 400 licensed osteopaths. Beyond this group there are approximately 2000 chiropractors, some of whom have been practicing for many years under what they choose to

term "practice without benefit of law." In something like twenty-three out of the last thirty years, this group has brought pressure for legislation to license chiropractors, and from time to time they have succeeded in the passage of their bill in one or the other branch of the Legislature. This year, although again defeated, they came extremely close to succeeding.

The interesting fact is that here is a relatively small group that, by persistence and an extremely well organized lobby involving elaborate testimonials and highly organized support from a relatively small proportion of the population, threatens to achieve its objective. In my opinion and that of many others, the licensing of this group to diagnose and treat illnesses of all types, with insufficient training and through the use of methods that we consider to be essentially unscientific, would constitute a step backward rather than forward in the state's responsibility for protecting public service. What they cannot achieve on the basis of scientific justification, however, they may perfectly well achieve eventually through the process of attrition, in which they exhaust the patience of the Legislature and in which the large mass of the public is more or less apathetic.

In this connection, it is interesting to note that the State Chapter of the American Federation of Labor threw its weight behind this bill in what appears to be a misguided attempt to bring about improved services for the workers whom they represent. Their attitude was obviously based on what might be regarded as a failure of the medical profession to recognize the painful and disabling effects of minor back injuries sustained in industry. These often do not present signs and symptoms sufficient to permit acceptance under workmen's compensation. Similarly, and not infrequently, I suppose, these patients may have been summarily dealt with at the hands of physicians who have been beset by the problem of malingering. It appears, however, that they have been more sympathetically received by the chiropractor and quite possibly given some relief through his manipulations.

Another example of the activity of pressure groups in the medical field, which was successful, relates to the Emergency Maternity and Infant Care Program, sponsored by the federal government through the United States Children's Bureau. As you may recall, in the early stages of this program considerable controversy arose over the attempts on the part of the Children's Bureau and certain of the states to set standards limiting the provisions of this program to the services of doctors of medicine. It was not long, however, before a small but highly organized lobby, supported primarily, I believe, by the American Osteopathic Association, succeeded in having the authority for such restriction stricken from the powers of the Children's Bureau. This they achieved through

introduction into legislation of phraseology to the effect that the wife of a serviceman must have the privilege of choosing the "practitioner of her choice," provided that state laws were complied with

Although I do not wish to embark on the controversial subject of the relative merits of the training of osteopaths and doctors of medicine, the important point is that to obtain its objectives this particular group succeeded in defeating measures that were intended to protect the quality of medical care being provided to wives of servicemen. In so doing, they opened the door for inclusion under the provisions of this program of that large variety of practitioners and cultists who we all know are permitted to practice in some states

With respect to the acceptability of a national medical-care program, there will be certain fundamental differences in the manner in which such a program impinges on the interests of the medical profession on the one hand and of the consumer public on the other. Obviously, the public will show its greatest concern over two questions — first, whether what it regards to be adequate medical services are physically available, and second, whether they are within economic reach. In general, unless medical facilities are totally lacking, it seems that the public is likely to address its primary consideration to the economic aspects — witness the current increase in the public support of voluntary hospitalization-insurance and medical-insurance schemes

What the public accepts as good for it in terms of quality as well as quantity of care, however, will probably be determined more by a superficial comparison of the facilities in the community with those in other communities of a similar nature than by any expert evaluation of the services actually available. And in the field of preventive medicine, of course, other than in connection with traditional public-health measures, there is a great lack of public understanding

I recall the surprise of a young lawyer in the Army returning home on leave who occupied the seat beside me on a plane not long ago. We fell to discussing the problem of medical care, and he seemed quite well informed. In common with most people, however, he believed that voluntary health insurance, supplemented by tax-supported care for the indigent, was pretty well on its way and that it left little to be desired. I was pleasantly surprised and encouraged by his change of attitude when I pointed out to him many of the facts that have already been covered in this series of lectures in relation to the inadequacy of facilities, the varying degrees of skill and opportunity to acquire and to maintain skill on the part of men in practice, the general absence of any systematic way of providing consultation services and specialist services other than in the large centers and the fact that the schemes that seemed to him to provide such a complete answer have fallen far short of doing so

We cannot, however, hope to reach a large number of people with such a direct approach. We must be prepared to accept the fact that it probably will be easier to satisfy the public as it currently, and somewhat superficially, sees its needs than it will be to obtain public support of the type of program that will be in the best interests of the public well-being in the long run

So far as the medical profession is concerned, acceptance of any sort will be difficult to predict. Consider, for example, the conclusions that we should have been obliged to draw if faced with this question ten years or so ago. We should have had to expect a complete lack of medical acceptance of hospitalization insurance or voluntary medical-indemnity insurance. Both these were formally resisted by the organized profession, but both of them are endorsed by it today. Similarly, at the time of its inception the Emergency Maternity and Infant Care Program was violently resisted by medical societies throughout the country, some of which held out until growing public opinion forced them to reverse their views. In spite of this, the program is now a going concern, widely and not infrequently enthusiastically accepted by physicians who are practicing under it. To be sure, important modifications have contributed to its acceptance, but it still is much different from the form that these groups in their first demands would have had it take

These experiences lead to the conclusion that perhaps the medical profession is far more socially minded and far more willing to co-operate with logical and well planned steps of a progressive nature than those who have been leading the opposition to change and progress would care to have us suspect. I have proceeded over a period of years in the conviction that this is true, and I am happy to say that my experience has borne it out.

Certainly the average physician is far too intelligent to accept for long the almost childish manner in which the proponents of reactionism have dealt with him. It appears that all that has prevented the physician from penetrating such methods sooner has been the fact that he has been extremely busy and has usually given superficial, transient and often emotional acceptance to such leadership. But when faced with the real issue and the grave necessity of acting in the face of it, I am confident that he will vindicate himself

I do not wish to be understood as taking the view that there are no grave problems involved and that the practicing physician should not be concerned, or that there is no danger of the introduction of unreasonable practices through the bureaucratic control of medicine. Judging from the patterns of past experience, there is undoubtedly reason for concern, but this danger will be far less, and probably need not materialize at all, if the medical profession will assume a vigorous and constructive role in

guiding the form of the impending changes that are of such importance to it

There seems to be great fear of governmental control over the physician's salary check and of interference between him and his patient in the monetary contract area, as well as apprehension that a system of salaried positions would result in suppression of the physician's individuality and his opportunity to pursue his work with energy and freedom, and that he would be badly paid

My own experience provides a case in point I have been a salaried employee with the government of the State of New York for almost ten years I am neither so rich as some of my classmates nor so poor as others Not once during the ten years of my employment have I felt the slightest impact of a political nature Although the question of freedom to work as one wishes is probably a matter that resides as much with the individual as with the system, I have found in the conditions of my employment even greater and less restricted opportunity to develop my interests and to expend my energies in directions that I consider to be worthwhile and productive than I encountered during the period of my private practice

I have never been able to understand the insistence of fellow physicians on the importance of the privilege of negotiating a direct financial arrangement with their patients I can recall vividly the extreme distaste with which, as a young man opening an office, I discussed the matter of compensation with my first patient Somehow or other, it did not seem compatible with the whole philosophy that had stemmed from my training and experience up to that time, and I had a haunting feeling that I should pay the patient for the privilege of working on him those skills that, to me, were a matter of such interest and personal satisfaction

From a somewhat less emotional and perhaps more practical point of view, it certainly seems that the medical profession would do well to look at the economic aspects of medical care from a strictly realistic angle If we were to assume that the cost of medical care is comprised primarily of physicians' fees, which, of course, it is not, — and that the values in medical service are comparable to a manufactured product in the luxury class, — which they are not, — the medical profession would be justified in insisting on its right to name its price and to control the conditions under which this product is purchased

But, obviously, we cannot regard any facet of the field of medical service in such a narrow light The product of the physician is not a luxury, it is a necessity In committing himself to a life of service in this field, the physician automatically assumes public responsibility, and in a sense, his life is no longer his own so long as he chooses to practice his profession These things being so, if the economic aspects of medical service are such as to stand in

the way of its complete accessibility to the public, I do not see how the physician can, in good faith, place his personal fears and considerations above changes that will serve the greater need Even granting that he should do so, and that all of the more than 170,000 physicians in the country were unanimous in their point of view, I do not see how the medical profession could expect, should it come to a battle, that their small voice would carry much weight against the interests of 140,000,000 people

On the other hand, the public is not competent to judge the extent of its technical needs or to evaluate the quality of service required or being provided Just as truly as it has the power to control the economic issue, it is powerless to develop and control the quality and equitable distribution of the services it needs At this point it must enter a partnership with the medical profession By the force of this very fact, the medical profession faces a great responsibility and is assured an opportunity, if it wants it, to build into any program provisions for the highest standards for service and continued development Medical acceptance should be given to nothing short of this

The plan must contain the substance for authority, responsibility and orderly administration This area in planning is almost sure to give rise to great controversy It is the area in which the medical profession fears that there will be created a dominating bureaucratic or political control, it is the area of potential regimentation, the danger point in what is so frequently and yet ambiguously referred to as "state medicine" It is the zone of fear because the reasons for it and the potential manner of its conduct are so completely misunderstood

The history of the process of growth from almost any angle, physical or sociologic, reveals the same fundamental patterns from the period of rudimentary beginnings through expansion, in which trial-and-error is the principal controlling force, to eventual development into a system or a series of complex relations that is likely to be cumbersome and confused because of its size and its overlapping and conflicting activities

At such a stage, organization becomes essential to survival This has been true of the growth of our cities, our schools, our banking system, our transportation, our industry, our employment As these have evolved from simple beginnings into more complex structures, certain forms of organization have had to be introduced This organization is a form of government

Similar problems of growth have arisen in relation to the distribution of medical services, preventive medical and public-health services and hospital services The point has been reached at which there is a pressing need for an over-all master plan for the Nation, for the states and for the major subdivisions of the states that will incorporate patterns for the co-ordination and conduct of these services

in their proper relation to each other and to the other operating forces in the social structure

There is often confusion with respect to the functions of leadership versus those of authority and administration, but these are not synonymous terms. The medical profession outside of government may very well be so intimately and thoroughly concerned with the affairs of practice, teaching and research that it cannot be expected to develop either the skill, the time or the interest to assume responsibility with respect to authority and administration. Although the profession must recognize its limitations in this respect, it should also recognize the importance and the significance of the contribution that can be made by government—because this is the proper function of government.

It is a peculiar anachronism that while we stand staunchly behind our belief in the democratic system and are now fighting for it, many of us simultaneously deprecate and abuse it by our words and attitudes. Why has organized medicine acquired such a violent, almost reflex response to the word "government," as though assuming that government is inevitably evil? Evidently, it is all right for government to be concerned with matters related to other people, but not for it to set its hand in any way on the affairs of medicine.

Pursuing this line of reasoning, we are obliged to conclude that the medical profession must either believe that it is capable of meeting the needs of the future under circumstances that will permit it to act as its own administrative agent and endow itself with the necessary authority or that it does not recognize the need of administrative functions in the manner in which I have described them. I can only assure you that the task of steering the ship of progress through the trials and obstacles that will lie in its charted course are, in this case, not matters of minor consideration. They will require the exercise of rare judgment in trained hands.

The medical profession makes much of its right to lead, and I too believe this, but we can properly raise the question of where this leadership lies or what its value in respect to the problems ahead is. Are we to look for it from the American Medical Association, which has a long record of inaction and negativism with respect to progress in this field? Are we to look for it from groups such as the newly organized Association of American Physicians and Surgeons, which, as you may recall, is attempting to rally physicians under the banner of organized passive resistance to any government-sponsored medical-care program?

The positions of these groups certainly do not constitute auspicious bridgeheads from which to expect to advance in the areas to which we are addressing ourselves. I believe, however, that true leadership from within the medical profession can and will be found, and that in its over-all planning and in developing the mechanics of administration govern-

ment should not be permitted, as an agent of the public interest, to proceed in the absence of such medical leadership.

Not so long ago I attended a meeting of a committee of a major national medical group at which problems arising from some of the existing federal programs in the field of medical care were under consideration. The purpose of this meeting was to establish patterns for so-called "co-ordinated action" between this national group and the controlling federal agency. There was a strong inclination on the part of the practicing physicians present to set up a special committee and to place before the federal agency what would have been little less than a demand that in the future this agency should call regular meetings of the special committee for the purpose of submitting its proposed policies for criticism and review. I am a strong advocate, as should already be clear, of medical co-operation with government and of the increasing influence of the medical profession in the control of medical affairs, but I opposed this suggestion. My opposition was conditioned by the belief that the proposed relation was essentially a negative one, based on the expectation of antagonism, and that although it might succeed in lessening some of the undesirable features of a potentially bureaucratic program, it would miss its real opportunity. In its place, I believed that it would have been better to have advocated a constant, co-operative working relation in which planning was mutually undertaken and in which the physicians were consulted during the formative stages of planning before conclusions had been reached and plans already drawn that would tend to make discussion become criticism and co-operative effort more or less futile.

It seems evident that no plan can succeed that does not embrace provisions for authoritative control and skillful administration. This I believe to be the function of good government. But equally I believe that good government must provide for the influences of effective guidance and leadership on the part of those who have the most to contribute. In the problem under discussion this would mean medical guidance and leadership.

The plan must be flexible with respect to local situations and future developments. This final principle is primarily a philosophy of planning, but it is also a test of the sincerity of purpose of the persons developing the plan. The plan at the national level, it seems to me, must be so fundamental and restrained in its approach to detail that flexibility will not constitute a problem. It is at the state and local levels, where working plans must be devised within the broad national pattern, that planned flexibility becomes a requisite.

Let me illustrate. A given state may start out with an attempt to set up a pattern of medical and health centers based on the health-center concept. Well and good. But supposing it en-

courages a group of hospitals to avail themselves of federal grants and postwar construction funds, only to find that it has gone ahead too rapidly and developed the centers in poor localities or in areas where they are not required. The state would then be confronted with a frozen front involving large investments of public funds and equally large and immovable investments in local public interest. The state program in such an instance would suffer from poor planning and inflexibility. On the other hand if the plan had developed its physical system in the wake of rather than ahead of its services, or at least a reasonably accurate concept of the details of such services, it would have retained flexibility during a critical period. Moreover, the services, not the brickwork, would remain the focal point — obviously a situation more favorable to such changes as the future might necessitate.

I have somewhat the same concern with respect to the potential rigidity of voluntary hospital and other insurance plans. Good as they may now seem, they are not the answer to the total problem and they may become obstacles rather than aids to further progress unless their limitations are clearly recognized by those sponsoring and controlling them. Although such insurance plans may help to meet the costs of medical care, they will do little to improve its quality or to bring about a better distribution of special skills and facilities. Also, they may divert public enthusiasm from the more fundamental issues because they are a sort of halfway measure in the right general direction. Once they are well under way, with large investments and a large following, they may well stand in the way of rather than assist further progress unless open-mindedness and an unusual degree of social consciousness are written into the substance of their charters.

The need for flexibility will run through many other aspects of planning that embrace experimental or temporary expedients. For example, it will probably be necessary, strictly as a matter of acceptability, to employ a fee-for-service basis for compensating physicians at the outset. Yet experience has clearly demonstrated that this is not the best solution, and room should be left for further changes as opportunity may present and experience may justify.

As has already been stated, flexibility in planning is almost an abstract quality — a matter of vision and sincerity. Yet no plan will be realistic that lacks it.

* * *

In preparing the material for this discussion I had both a purpose and a hope in mind. My purpose was to try to give you a glimpse of the problems surrounding the field of medical care as seen through the eyes of a physician in government — in the specialty of medical administration, if you will permit me to call it such.

My hope was simple and not too visionary. I hoped, and still hope that you — or at least some of you — will carry this discussion much farther in your own minds and that it may prove of assistance to you in the continued development of your interest in the medical needs of the Nation. And I hope that you will be ready to carry your share in assuring that whatever steps are taken shall be forward steps.

CASE 32091

PRESENTATION OF CASE

An eighteen-year-old boy was admitted to the hospital complaining of pain in the left arm.

Four months before admission, while roller skating, he fell, experiencing a sensation of something snapping in the left back under the scapula, this being accompanied by pain. On arising, he was unable to use the left arm because of pain in the shoulder. This pain was aggravated by coughing and radiated to the anterior chest. During the next two weeks, the shoulder pain subsided and he recovered full use of the arm, the chest pain, however, was still present when he coughed. Three weeks before admission he first noticed prominent veins in the upper portion of the left arm. At the same time a constant dull ache appeared along the posterior portion of the left upper arm and became progressively severer. Ten days before admission he was examined by his draft board and advised to go to a hospital immediately.

Two and a half years before admission the patient had migratory joint pains, as well as a red rash on the anterior aspect of both legs. A cardiac murmur was heard at that time but later disappeared. He had had scarlet fever at the age of four years.

Physical examination revealed a well developed and well nourished boy in no acute discomfort. The pupils were regular and equal and reacted to light and accommodation. The thyroid gland was not palpable. The trachea was in the midline. In the left anterior triangle of the neck was a firm mass about 2 cm in diameter, which was continuous with a larger mass in the left supraclavicular fossa near the midline, the larger mass was firm, nontender and irregular. A systolic bruit was heard over an area including the larger mass and the left clavicle. There was dullness to percussion over the apex of the left lung, more marked posteriorly. The breath sounds were absent in this area, with decreased tactile fremitus, otherwise the lungs were clear. The heart was negative. Discrete hard nodes about 5 mm in diameter were palpated in the left axillary region. The abdomen was negative. The left hand

was cold and blue. The biceps and triceps reflexes could not be elicited on either side.

The temperature was 98.6°F, the pulse 80, and the respirations 20. The blood pressure on the right was 120 systolic, 80 diastolic, and on the left, 116 systolic, 90 diastolic.

The red-cell count was 4,700,000, with 15 gm of hemoglobin. The white-cell count was 11,100, with 67 per cent neutrophils. The urine and stools were normal. An x-ray film of the chest revealed a soft-tissue mass measuring 8 by 6 cm in the left upper chest. It was slightly lobulated and continuous with the lateral chest. The remainder of the lung fields was clear. The heart, aorta and diaphragmatic shadows were not remarkable. The first rib on the left was not clearly visualized in its anterior two thirds, but there was a fracture at the junction of the middle and posterior thirds, the second rib on that side was not remarkable. Pulsation of the mass was not noted fluoroscopically.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR. CLIFFORD C FRANSEEN: May we see the x-ray films?

DR. MILFORD D SCHULZ: A soft-tissue mass lies in the apex of the left chest laterally and anteriorly. The anterior and lateral portion of the first rib is destroyed (Fig 1).

DR. FRANSEEN: Where is the fracture?

DR. SCHULZ: I cannot see the fracture. The mass appears to be outside the lung.

DR. FRANSEEN: The age of the patient is of primary importance in any bone tumor. I shall discuss this point later. Another important bit of evidence is the fact that he fell and had a snapping pain in the left scapular region. That pain could have been due to a pathologic fracture of the first rib. If there was a fracture, as was interpreted, the pain later eased up some but was still present when he coughed. The next episode was three weeks before admission when he first noticed prominent veins in the upper portion of the left arm, with an ache posteriorly. All this was undoubtedly due to the position and size of the tumor, pressure on the subclavian vein causing the prominent veins. The earlier findings of migratory joint pains and a cardiac murmur apparently have no relation with the present problem.

So far as the physical examination goes, the important thing is the 2-cm mass that was continuous with a larger mass in the left supraclavicular fossa. The fact that it was continuous is perhaps important because we are interested in knowing whether this was a tumor that had metastasized or a primary tumor that had extended in this region, this one point alone may be significant in the differential diagnosis. A systolic bruit was heard over the mass, which can be accounted for on the basis of pressure on the vessels, particularly on the subclavian artery.

Nodes 5 mm in diameter were found in the left axillary region, one cannot put much importance on nodes of this size in the axilla. The arm reflexes could not be elicited, undoubtedly because of pressure on the brachial plexus.

This seems clearly to have been a tumor. What organ did it originate in? We can exclude the lung

involvement of bone usually comes after the disease has been progressive for a year or two, and then not by direct extension, as this must have been. Still other extraosseous tumors that could have invaded the bone are the lymphangiomata and the hemangiomas, but they do not seem likely. There is nothing to suggest a tumor of neurogenic origin. The

FIGURE 1

by the x-ray interpretation. Could it have arisen in the pleura? The tumors that might come from the pleura in this region are the endotheliomas and the sarcomas. They are frequently associated with effusion, which was not present here. Was this something outside the bone invading it secondarily or was it primary in the bone? Could it have originated in the lymph nodes and then have invaded the bone? The first thing to think of at this age is Hodgkin's disease. We know that such a tumor frequently invades bone, but to me this is not the picture of Hodgkin's disease. Hodgkin's in-

neurologic signs here can be interpreted on the basis of pressure. One cannot entirely exclude fibrosarcoma, except to some extent on the appearance of the x-ray films, it is conceivable but unlikely.

If we consider this to be a lesion originating in the bone we must ask, as Dr. Channing Simmons has taught us, Was it infectious? Was it metabolic? Was it neoplastic?

There is not much about the appearance of the mass or the systemic reaction to suggest that it was infectious — pyogenic, tuberculous or syphilitic. No serologic test is reported, but it is safe to say

CASE 32091

PRESENTATION OF CASE

An eighteen-year-old boy was admitted to the hospital complaining of pain in the left arm.

Four months before admission, while roller skating, he fell, experiencing a sensation of something snapping in the left back under the scapula, this being accompanied by pain. On arising, he was unable to use the left arm because of pain in the shoulder. This pain was aggravated by coughing and radiated to the anterior chest. During the next two weeks, the shoulder pain subsided and he recovered full use of the arm, the chest pain, however, was still present when he coughed. Three weeks before admission he first noticed prominent veins in the upper portion of the left arm. At the same time a constant dull ache appeared along the posterior portion of the left upper arm and became progressively severer. Ten days before admission he was examined by his draft board and advised to go to a hospital immediately.

Two and a half years before admission the patient had migratory joint pains, as well as a red rash on the anterior aspect of both legs. A cardiac murmur was heard at that time but later disappeared. He had had scarlet fever at the age of four years.

Physical examination revealed a well developed and well nourished boy in no acute discomfort. The pupils were regular and equal and reacted to light and accommodation. The thyroid gland was not palpable. The trachea was in the midline. In the left anterior triangle of the neck was a firm mass about 2 cm in diameter, which was continuous with a larger mass in the left supraclavicular fossa near the midline, the larger mass was firm, nontender and irregular. A systolic bruit was heard over an area including the larger mass and the left clavicle. There was dullness to percussion over the apex of the left lung, more marked posteriorly. The breath sounds were absent in this area, with decreased tactile fremitus, otherwise the lungs were clear. The heart was negative. Discrete hard nodes about 5 mm in diameter were palpated in the left axillary region. The abdomen was negative. The left hand

was cold and blue. The biceps and triceps reflexes could not be elicited on either side.

The temperature was 98.6°F, the pulse 80, and the respirations 20. The blood pressure on the right was 120 systolic, 80 diastolic, and on the left, 116 systolic, 90 diastolic.

The red-cell count was 4,700,000, with 15 gm of hemoglobin. The white-cell count was 11,100, with 67 per cent neutrophils. The urine and stools were normal. An x-ray film of the chest revealed a soft-tissue mass measuring 8 by 6 cm in the left upper chest. It was slightly lobulated and continuous with the lateral chest. The remainder of the lung fields was clear. The heart, aorta and diaphragmatic shadows were not remarkable. The first rib on the left was not clearly visualized in its anterior two thirds, but there was a fracture at the junction of the middle and posterior thirds, the second rib on that side was not remarkable. Pulsation of the mass was not noted fluoroscopically.

An operation was performed.

DIFFERENTIAL DIAGNOSIS

DR CLIFFORD C FRANSEEN: May we see the x-ray films?

DR MILFORD D SCHULZ: A soft-tissue mass lies in the apex of the left chest laterally and anteriorly. The anterior and lateral portion of the first rib is destroyed (Fig 1).

DR FRANSEEN: Where is the fracture?

DR SCHULZ: I cannot see the fracture. The mass appears to be outside the lung.

DR FRANSEEN: The age of the patient is of primary importance in any bone tumor. I shall discuss this point later. Another important bit of evidence is the fact that he fell and had a snapping pain in the left scapular region. That pain could have been due to a pathologic fracture of the first rib. If there was a fracture, as was interpreted, the pain later eased up some but was still present when he coughed. The next episode was three weeks before admission when he first noticed prominent veins in the upper portion of the left arm, with an ache posteriorly. All this was undoubtedly due to the position and size of the tumor, pressure on the subclavian vein causing the prominent veins. The earlier findings of migratory joint pains and a cardiac murmur apparently have no relation with the present problem.

So far as the physical examination goes, the important thing is the 2-cm mass that was continuous with a larger mass in the left supraclavicular fossa. The fact that it was continuous is perhaps important because we are interested in knowing whether this was a tumor that had metastasized or a primary tumor that had extended in this region, this one point alone may be significant in the differential diagnosis. A systolic bruit was heard over the mass, which can be accounted for on the basis of pressure on the vessels, particularly on the subclavian artery.

superspecialization if I were called on to choose a surgeon to operate in such a case, I should not know whom to call, because the tumor involved the chest, the neck and all sorts of organs that are unfamiliar to most of us in the ordinary routine run of surgical practice

I made an incision over the clavicle and resected the medial two thirds of that bone. That exposed the subclavian vessels, which were flattened and compressed to such an extent that it was difficult to see how any blood could get through either the vein or the artery. The tumor arose in the first rib and seemed to involve the second rib, although we thought that perhaps the second rib was merely pressed on by the tumor. For a long time I was uncertain whether to remove it, but ultimately got so far that I had to take it out. This involved tying the thoracic duct and removing long segments of the subclavian and axillary arteries, including the main collateral vessels and one or two others. In so doing, I thought that we would produce a permanent disability to the patient's arm, but since we were dealing with a malignant tumor, this had to be done. We forcibly retracted the brachial plexus. On opening the chest I discovered that the tumor had invaded a portion of the upper lobe of the left lung, and this part of the lung was removed. When we got down to the point where I thought that I had dissected away most of the tumor, I observed what appeared to be invasion of the scalene muscles beyond where I could trace it. So I took out a tremendous mass of tissue including a tumor twice the size of what it appeared to be by x-ray, along with the piece of lung and the large sections of artery and vein. We could look into the patient's chest and see the heart and diaphragm from above. In order to improve the collateral circulation to the arm, I did a sympathectomy, removing the second and third dorsal ganglions.

The amazing thing is that following operation the patient had no trouble with the arm, although it was slightly weak, he used it well.

CLINICAL DIAGNOSIS

Chondrosarcoma of rib

DR FRANSEEN'S DIAGNOSIS

Chondrosarcoma of rib

ANATOMICAL DIAGNOSIS

Ewing's sarcoma of first rib, with extension into mediastinum, lung and neck

PATHOLOGICAL DISCUSSION

DR CASTLEMAN The gross appearance was that of a meaty tumor, not the gelatinous type that one sees in a chondrosarcoma. There was tumor at the resected edge where Dr Sweet had cut across, and histologic examination showed a rapidly growing

Ewing's tumor. Following operation the patient received x-ray treatment with the million-volt machine. He may do well for a while, although I do not know of any cures of Ewing's tumor except one that Dr Schulz told me about yesterday.

DR SCHULZ In 1939, at the Huntington Hospital, a boy, then five years old, was seen in whom we discovered, more or less by accident, a tumor involving the right eighth rib. The lesion was biopsied, and sections were sent to quite a number of pathologists, who made the diagnosis of Ewing's tumor. X-ray treatment with the Huntington Hospital's million-volt machine was given, and he has been well since. This is one of the rare cases of Ewing's tumor in which the victim has survived for more than five years.

DR CASTLEMAN The tumor was not removed?

DR SCHULZ No.

DR FRANSEEN It would be interesting to know whether the mass in the anterior triangle was a mediastinal node that had become continuous or was part of the main tumor.

DR CASTLEMAN No lymph nodes were involved. The tumor in the neck was an extension of the primary lesion.

CASE 32092

PRESENTATION OF CASE

A fifteen-year-old girl was admitted to the hospital complaining of swelling of the face and legs.

One year before admission, following an upper respiratory infection, edema of the face, hands and ankles appeared, associated with dyspnea and orthopnea. There was no oliguria or hematuria. At another hospital the blood pressure was found to be 145 systolic 100 diastolic. An intravenous pyelogram revealed normal calyces, pelvis and ureter on the left, there was no function on the right. A retrograde pyelogram revealed a small contracted right kidney, with normal calyces, pelvis and ureter. No calculi were found. While the patient was in the hospital, the blood pressure varied from 140 systolic, 90 diastolic, to 170 systolic, 40 diastolic. The nonprotein nitrogen varied from 36 to 49 mg per 100 cc, and the serum protein from 3.6 to 4.3 gm. Albuminuria was constantly present. At the time of discharge, she was free of edema and felt well. She remained well until two weeks before admission, when, with the development of an upper respiratory infection, the same symptoms reappeared, accompanied by pain in the abdomen and in the costo-vertebral angles. There were no urinary symptoms. She felt fatigued, and a cough with tenacious sputum developed.

The past history was noncontributory. She had not had scarlet fever.

Physical examination revealed a well developed

that it was done, because it is almost an invariable rule in any case of bone tumor to rule out syphilis, which can simulate most of these lesions. Another condition that comes to my mind, because I was caught on it three years ago, is an eosinophilic granuloma of the rib. That condition, however, shows a somewhat punched-out area in the rib, and I know of no case in which a tumor mass has been produced. Thus, there is nothing in this case to suggest an infection, nor is there anything to suggest a metabolic disturbance.

So we come to the fact that it must have been neoplastic. Was it benign or malignant? The regular contour suggests a benign lesion. Was it metastatic or primary? The metastatic lesions that occur at this age are few. Ewing's tumor can metastasize to a rib, the other metastatic lesions that occur in children, such as the neuroblastomas, usually appear at an earlier age, and there is no clinical or other evidence to suggest that metastases had occurred.

This then appears to have been a primary tumor, and the differential diagnosis lies between myeloma, Ewing's tumor and osteogenic sarcoma. We can discard myeloma because the great majority of them occur in patients over forty and the tumors are usually multiple. The only thing that suggests it is the pathologic fracture, because statistically 50 per cent of cases of myeloma have pathologic fractures at some time during their course, frequently in the rib. In this case I believe that we can exclude it on the basis of age alone.

How about Ewing's tumor? Ewing's tumor originates in the spongiosa of the bone and is not a cortical destructive lesion, therefore not many pathologic fractures occur with it. Another possible reason for the absence of fractures in Ewing's tumor is that pain is so prominent that the bone is protected, particularly the long bones.

When osteogenic sarcoma does occur in the rib, it is usually the sclerosing type, but the chondroblastic type is likelier to have pathologic fractures because of the bone-destructive effect.

So I have narrowed the diagnosis down to osteogenic sarcoma, with its variations, and Ewing's tumor. This patient was eighteen years old, an age group in which both these tumors occur, in Ewing's tumor 95 per cent of the patients are below twenty-five years of age. This site is rare in both tumors, although both do occur there. I have never seen a Ewing's tumor of the rib in this country, but I did see three in quick succession in Sweden — all rare diseases seem to come in groups of three.

The other thing to be considered in the differential diagnosis of this case is the presence or absence of metastases. Was the tumor mass in the anterior triangle of the neck a metastasis or was it continuous with the primary tumor? This is quite a long way for a tumor of the rib to extend, but it would be likelier in a case of Ewing's tumor than in one of osteogenic sarcoma. Metastases in osteo-

genic sarcoma are extremely rare. I have only seen two such cases — one a paravertebral metastasis and the other a case in which there were bone-forming metastases in the axilla. It does occur, however, as I have said, more commonly in Ewing's tumor than in osteogenic sarcoma. Ewing's tumor, as you know, is usually accompanied by a febrile reaction. This patient was in good general condition on physical examination. On a statistical basis, two thirds of all malignant tumors of bone are osteogenic sarcoma. If this was osteogenic sarcoma, what is the likelihood of the sclerosing form? Osteogenic sarcoma in the rib is usually sclerosing, but there is not much about the x-ray picture to suggest that this was a sclerosing type of tumor. The other form is chondrosarcoma or chondromyxosarcoma. From the evidence we have, I favor a primary tumor of the costal cartilage of the right first rib — a chondrosarcoma, possibly with myxomatous elements. As you know, such tumors invade along the rib, which makes it necessary to remove the entire rib. In any case, one should not be satisfied in removing the tumor alone, if possible, the entire rib should be removed.

DR BENJAMIN CASTLEMAN Dr Richardson, have you any comment?

DR WYMAN RICHARDSON This patient was on the medical service for a short time and I made a diagnosis of malignant tumor and yelled for Dr Simmons.

DR CASTLEMAN Dr Berg, you also saw this patient.

DR ROBERT L. BERG Dr Helen Pittman saw him on the first day and thought that a block resection should be done immediately because of the possibility of rapid extension. I think that we were all agreed on the diagnosis of malignant tumor, but like Dr Richardson, no one tried to be more specific.

DR RICHARD H. SWEET My point of view was much like that of Drs Franseen, Richardson, Pittman and Berg. It was obviously a malignant tumor. I made a preoperative diagnosis of chondrosarcoma, which is, in my experience, by far the most frequent primary malignant tumor of rib, as Dr Franseen has said, excluding multiple myeloma. Although he has not seen any cases of Ewing's tumor of rib in this country, I saw one case some years ago, but I still regard it as a rather unusual occurrence. These were the two tumors considered in differential diagnosis.

From the clinical aspect of the case it was obvious that we were dealing with a malignant tumor and that the prognosis was bad. But it seemed to me that, with a young boy of eighteen in a remarkably good state of health, we should make an attempt to remove the tumor. It so happened that the first-year anatomy class was watching the operation from overhead, and it turned out to be a remarkable lesson in anatomy. In these days of

before the final admission. It would be interesting to know whether albuminuria or hypertension persisted throughout the long asymptomatic interval. Two weeks before admission she again became ill, went downhill quickly in the hospital, and died six weeks after the return of symptoms.

The terminal uremia was typical of that seen in chronic glomerulonephritis, as well as in other types of chronic Bright's disease. Severe renal failure was shown by the low fixed specific gravity of the urine, the greatly diminished or absent excretion of dye in the renal-function test and following intravenous pyelography respectively, the markedly elevated nonprotein nitrogen, the lowered serum calcium, the elevated phosphorus and the lowered carbon dioxide content. The serum sodium and chloride values were within normal limits. The moderate anemia is a frequent finding in uremia.

Like the earlier episode, the onset of this illness, apparently an acute exacerbation of a chronic glomerulonephritis, accompanied an upper respiratory infection. She had a cough and raised some sputum, which showed Type 22 pneumococci on culture. The pleural fluid obscured both the physical and x-ray examinations and made it difficult to be certain whether or not these organisms were associated with a pneumonic process. The normal temperature and the only slightly elevated white-cell count suggest that no significant pulmonary infection was present.

Again, edema of the eyelids and face was a striking feature of the clinical picture, and the serum protein was somewhat low. Part of the generalized edema was due to cardiac failure, which will be considered later, but much of it was of the nephrotic type, a common feature of chronic glomerulonephritis. The patient had pain in the abdomen and costovertebral angles, which is often seen with an exacerbation of a chronic process of this sort.

The urinary findings are of interest. Albumin and white cells were found, although, despite the severe degree of renal damage that was present, no red cells or casts were seen. Presumably the marked pathologic changes in the kidneys in this terminal stage prevented the excretion of these elements.

Congestive heart failure, so often seen in chronic glomerulonephritis, was manifested in this patient by dyspnea, orthopnea, dependent edema, bilateral pleural effusions, enlarged hilar shadows, ascites, a gallop rhythm and an enlarged tender liver. The heart size could not be definitely determined by physical or by x-ray examination. Liver function as tested by the cephalin-flocculation test, the prothrombin time and the van den Bergh reaction, was normal. Digitalis and Mercupurin gave some

diuresis, but death occurred due to a combination of uremia and cardiac failure.

CLINICAL DIAGNOSES

Chronic glomerulonephritis
Uremia
Cardiac failure

DR LINENTHAL'S DIAGNOSES

Chronic glomerulonephritis, with uremia
Congestive heart failure
Congenital hypoplasia of right kidney

ANATOMICAL DIAGNOSES

Chronic glomerulonephritis of left kidney
Congenital hypoplasia of right kidney
Congenital malformation of left kidney
Cardiac hypertrophy, hypertensive type
Pericarditis, uremic
Anasarca
Bronchopneumonia

PATHOLOGICAL DISCUSSION

DR TRACY B. MALLORY: Dr Linenthal has accurately predicted the pathological findings in the kidney. The right kidney was extremely small, weighing only 10 gm. The pelvis was quite normally developed, but the renal parenchyma consisted only of a shell 2 mm in width in which no structural detail, such as differentiation into cortex and medulla, could be observed. Microscopically the sections showed only a single glomerulus and a mass of undifferentiated tubules filled with dense colloid casts. Except for a slight pyelitis there was no evidence of inflammation, and the picture is that of a congenitally hypoplastic kidney. The left kidney was also markedly abnormal in development, consisting of two almost separated lobes. It weighed 95 gm. The capsule stripped with difficulty and left a finely granular surface. Microscopical examination revealed great destruction of the glomeruli, widespread interstitial fibrosis and marked dilatation of the persisting tubules. The blood vessels showed extensive secondary sclerotic changes. There was no evidence of acute progressive glomerulitis. The chronicity of the process answers Dr Linenthal's question about the first admission. It seems quite certain that she must have already had a chronic process at that time.

The other findings at autopsy were such as might be expected in a case of chronic nephritis. There was a terminal fibrinous pericarditis, and the heart was slightly hypertrophied. The lungs showed edema and focal pneumonia. There was generalized edema.

and well nourished girl who was dyspneic and orthopneic and had a hacking cough productive of yellow, mucoid sputum. She was not cyanotic or jaundiced. The skin was pale. The eyelids and face were edematous. The tongue was dry and coated. A few small cervical lymph nodes were palpable. The heart was questionably enlarged to the left. There were no thrills or murmurs. Dullness to percussion, diminished breath sounds and moist rales were found over the right base posteriorly. The abdomen was diffusely tender, so that palpation was unsatisfactory. The liver edge was tender and palpable three finger-breadths below the right costal margin. Tenderness was also elicited over both costovertebral angles. The sacrum and lower extremities were markedly edematous.

The temperature was 98.6°F, the pulse 70, and the respirations 20. The blood pressure was 145 systolic, 114 diastolic.

The red-cell count was 3,500,000, with 10.2 gm of hemoglobin. The white-cell count was 10,700, with 74 per cent neutrophils. The urine was cloudy and yellow, with a specific gravity of 1.008. It gave a +++ test for albumin, and the sediment contained 50 to 60 white cells per high-power field, there were no red cells or casts. The Sulkowitch test for urinary calcium was negative. The non-protein nitrogen was 125 mg per 100 cc. The serum protein was 5.3 gm per 100 cc, with 3.1 gm of albumin and 2.2 gm of globulin. The serum cholesterol was 164 mg per 100 cc, the sodium 138.8 mEq and the chloride 99 mEq per liter, and the calcium 7.6 mg and the phosphorus 6.5 mg per 100 cc. The prothrombin time was 27 seconds (normal, 18 seconds). A cephalin-flocculation test was negative in twenty-four and forty-eight hours. The van den Bergh reaction was normal. A blood Hinton test was negative. A throat culture was negative for beta-hemolytic streptococci. A sputum culture showed rare beta-hemolytic streptococci and a moderate number of Type 22 pneumococci. The urine was sterile.

A chest plate showed a considerable amount of pleural effusion bilaterally. The hilar shadows were quite prominent, but the lung fields were obscured in their lower half by the fluid. The heart shadow was not clearly outlined because of the adjoining density in the chest.

The patient was digitalized. She vomited occasionally. An electrocardiogram taken on the fifth hospital day showed sinus arrhythmia, with a rate of 100. QRS₁ was upright and low, T₁ flat, and QRS₂ slurred. The PR interval was 0.18 second. T₂ was low upright, QRS₂ slurred, T₂ slightly inverted, S prominent in CF₁, T flat in CF₁, and T low and upright in CF₂ and CF₃. Two days later a concentration test of renal function showed fixation of specific gravity at 1.006. A phenolsulfonephthalein test showed less than 10 per cent total excretion in two hours. The serum carbon dioxide content was

15.8 mEq per liter, and at that time the non-protein nitrogen was 50 mg per 100 cc. An intravenous pyelogram taken on the tenth hospital day showed extremely poor detail because of the large amount of fluid in the abdominal cavity. There was a small amount of gas in several loops of small intestine, without distention. The kidney shadows were not clearly outlined. Over a period of sixty minutes no dye was excreted by either kidney. The urinary passages were not outlined. Fair diuresis was obtained with Mercupurin, but nausea and vomiting persisted, the latter becoming projectile in nature.

On the nineteenth day the nonprotein nitrogen rose to 160 mg per 100 cc. The patient became unresponsive. A gallop cardiac rhythm appeared. She expired on the twenty-ninth hospital day.

DIFFERENTIAL DIAGNOSIS

DR ARTHUR J. LINENTHAL. This patient had renal disease, as manifested in the clinical picture of the illness one year before admission and in the final episode, which was terminated by a combination of renal and cardiac failure. The problem is to determine the nature of the renal lesion.

The nephrotic picture of the disease, as evidenced by marked generalized edema, suggests glomerulonephritis rather than pyelonephritis or nephrosclerosis. In addition, the youth of the patient is against a primary vascular disease, and at no time was there evidence of urinary-tract infection. The edema and marked albuminuria raise the possibility of a degenerative disease of the tubules, that is, nephrosis, but the elevated blood pressure, evidence of renal failure and normal serum cholesterol are against this diagnosis. The pyelographic demonstration of a small contracted nonfunctioning right kidney is of interest, but the absence of obstruction or infection and the normal calyces, pelvis and ureter suggest that this kidney was congenitally hypoplastic and that this anomaly was unrelated to the renal disease, although the kidney was probably involved in the inflammatory process, which is typically bilateral.

In attempting to explain this patient's illness on the basis of glomerulonephritis, the question arises whether the episode one year before the final admission represented an acute process or an exacerbation of a chronic stage of this disease. The absence of hematuria is somewhat puzzling in either case. The relation to an upper respiratory infection and the edema, dyspnea, orthopnea, elevated blood pressure, albuminuria and slightly elevated nonprotein nitrogen are of little differential value. Aside from the rather low serum protein, which suggests a chronic process, there is nothing further to aid in the differentiation.

We are not told the duration of this first period of illness, but the patient recovered completely so far as symptoms are concerned and was well until shortly

elsewhere in this issue of the *Journal*, aggressive attempts should be made to publicize these facts among physicians, as well as among diabetic patients

More reports of the results of treatment in series of coma cases are needed to emphasize the serious prognosis in diabetic coma, especially in patients with unconsciousness and with complications. Laboratory facilities should be more generally available to all doctors for emergency determinations of the blood constituents, as aids both in diagnosis and in treatment. Prompt diagnosis and aggressive treatment in the early stages have been shown not only to relieve the acidosis but also greatly to enhance the patient's chance of recovery from an otherwise severe or fatal complication.

THE COMMITTEE ON GROWTH

IN THE past, the control and treatment of cancer has been attacked by many able men the world over, and it is unnecessary to point out that many notable advances have been made. It is true, however, that the problem of malignant neoplastic disease, which in essence is that of ceaseless, profitless and often uncontrollable growth, has been approached by individual groups of men with rather specialized training and abilities. There have been the pathologists, like the late Drs Mallory and Ewing, who defined and delineated groups of cancer, there have been the clinicians, who have studied the natural history of the disease and have worked out helpful and even curative surgical measures, there have been the radiologists and physicists, who have greatly advanced the technical weapons with which cancer may be attacked, there have been the geneticists, the biologists and the chemists, who have enriched knowledge of hereditary factors and carcinogenic agents, and there have been the public-health officials, who, through appropriate and legitimate propaganda, have educated the public to seek medical advice earlier and to accept more readily the available hospital facilities. But when all is said and done, it must be admitted that, as a general thing, these men, however able, worked in comparative isolation, each pursuing the line of investigation to which he was most suited and for

which he was best trained. This is not to say that their contributions were not of the first order — they were. The tactics were excellent, but the overall strategy was perhaps lacking or at best in the background.

As has been said, the essence of the problem is that of ceaseless, profitless and often uncontrollable growth. It is therefore gratifying that there has been created within the Division of Medical Sciences, National Research Council, the Committee on Growth, which as a body will function as a scientific adviser to the American Cancer Society. This committee is a true board of strategy, an integrating body composed of the foremost men in their respective fields. By their general direction and with their combined and unified help it may properly be hoped that the solution of the cancer problem is nearer at hand. Under a general staff headed by Dr Cornelius P Rhoads and including such outstanding scholars as Drs Dochez, Hastings, Sabin, Little and Winternitz, there are divisions of biology, chemistry, clinical investigation and physics. Within these divisions are panels covering such diverse departments as radiology, endocrinology, nutrition, enzymes, mutation and botany. Each of these panels, in turn, is headed and staffed by outstanding investigators, such as Drs Cowdry, Dubos, Albright and Castle. Presumably it is the intent of this excellent committee to integrate the existing investigations in the field of cancer and to initiate new ones. If such be the case, — and there is every reason to believe that it is, — the future of cancer investigation is bright indeed.

EARLY DIAGNOSIS AND TREATMENT OF DIABETIC COMA

DURING the seventy years that have elapsed since the discovery of the ferric chloride test for diacetic acid in the urine, intensive study of ketosis as it occurs both in diabetes and in nondiabetic states has greatly increased knowledge concerning its relation to the metabolism of carbohydrate, protein and fat

In diabetic coma the essential disturbance in carbohydrate metabolism is due to the relative or absolute lack of insulin. Ketosis and ketonuria follow the failure to utilize sufficient carbohydrate and the consequent increased formation of ketone bodies from fat. The discovery of ketonuria in a

diabetic patient should always be taken as an emergency sign indicating the need for further study of the patient and prompt treatment. Although tests for acetone and diacetic acid may be strongly positive in the urine of some patients who have not as yet developed severe acidosis, ketosis is eventually accompanied by dehydration and loss of base. Numerous methods for ascertaining the degree of acidosis have been employed, such as determinations of the total acetone bodies in the blood, of the hydrogen ion concentration of the blood and of the excretion of ammonia in the urine. The degree of acidosis may also be determined accurately by measurements of the carbon dioxide content of the blood. If the carbon dioxide content of the blood has fallen from the normal of 26 millimols per liter (60 volumes per cent) to the neighborhood of 13 millimols (30 volumes per cent), a moderate degree of acidosis is present. When it has fallen below 9 millimols, experience indicates that, if unconsciousness has not already developed, its onset is a matter of hours and that the terminal stage of shock and anuria is impending.

In a recent article by Almy, Swift and Tolst^{*} the value of determinations of the blood-sugar and of the blood-carbon dioxide levels in the treatment of diabetic coma is minimized. In their series, however, since only 19 out of 99 patients had the typical Kussmaul breathing of acidosis, it is evident that the series included a large number of extremely mild cases of ketosis, although chemical data are not given. Indeed, only 1 patient was unconscious, and several of 7 who died had complicated cases. A more general teaching is that diabetic acidosis and coma are emergency states in which a careful study of the patient and chemical determinations of the sugar level and for evidence of acidosis in blood and urine are essential to the best type of treatment. A diagnostic pitfall to be avoided lies in the fact that, although ketonuria at first may be excessive, in the more advanced stages with renal failure, ketone bodies are no longer excreted in the urine. More emphasis should be laid on early diagnosis of impending diabetic coma, since treatment with insulin at that time averts the later and more critical stages. As pointed out by Dr. Haigh in a letter published

PEPTIC ULCER AMONG SOLDIERS IN THE MEDITERRANEAN THEATER OF OPERATIONS

LIEUTENANT COLONEL JAMES A. HALSTED, M C, A U S, AND
TECHNICIAN (5TH GRADE) HENRY WEINBERG, MED DEPT, A U S

AT THE beginning of the war, it was thought that peptic ulcer would present a serious military medical problem. This has evidently been the case in Army hospitals and induction centers in the United States. Owing to rejections at induction and discharge from the service of patients in Army hospitals in the Zone of the Interior, the disease was not seen in the Mediterranean theater of operations with the frequency expected, particularly after the first year. At the Sixth General Hospital in North Africa, however, to which a considerable proportion of patients were sent for evacuation to the United States, an opportunity was presented between March, 1943, and January, 1944, to study an unusually large number of patients with peptic ulcer.

Several reports¹⁻³ have appeared regarding the incidence and clinical features of this disease as seen in Army hospitals in the United States and in overseas theaters. In the present report are presented data in 200 consecutive cases among enlisted men. In certain aspects, the disease in these cases appears to differ from that noted among recent inductees in Army hospitals in the United States.

We have been interested in two main aspects of the problem—the purely clinical aspects and the psychosomatic features. In connection with the latter, certain data have been obtained bearing on the question of whether the nervous tension of Army life is a factor in either the etiology or the course of the disease. In addition, observations have been made regarding the personality differences between patients with peptic ulcer and those with chronic psychogenic dyspepsia; these observations appear to be of practical value in differentiating the two disorders.

STATISTICS

The large number of soldiers with chronic epigastric distress admitted to the Sixth General Hospital in a period of ten months may be arbitrarily divided into those with peptic ulcer and those with dyspepsia not caused by ulcer, after excluding the cases in which the distress was caused by cholecystitis or some other abdominal disorder. Two hundred and twenty-four patients with proved

ulcer were admitted to this hospital, 24 of them were officers and are not included in this study. The exact number of patients with non-ulcer dyspepsia is not known, because many men had been on various services and had been discharged with varying diagnoses, particularly when the primary disorder was surgical, temporarily submerging the importance of the epigastric distress. A minimum figure, however, may be obtained from the total number of gastrointestinal x-ray examinations that were performed, since before disposition most of the patients with chronic indigestion were examined by x-ray in this hospital even though previously examined elsewhere. With the ulcer cases subtracted from the total number receiving gastrointestinal x-ray examinations, it is estimated that there were between 500 and 600 cases of non-ulcer dyspepsia. Thus, the ratio of ulcer to non-ulcer cases is about 1:3—a higher one than has been noted in most Army hospitals in the United States. The chief reason is that this hospital, being at the tip of a funnel for evacuation to the Zone of the Interior, received a considerable proportion of all ulcer patients in the theater. This ratio does not, therefore, signify that the incidence of peptic ulcer among soldiers with chronic epigastric distress is higher in the Theater of Operations than in the Zone of the Interior.*

*Since this paper was written we have had the opportunity to study patients with chronic dyspepsia at the Sixth General Hospital in Italy between July 1, 1944, and November 1, 1944. This hospital received patients from the front a few days after evacuation. Between November 1, 1944, and May 1, 1945, 350 patients with chronic dyspepsia were studied at a gastrointestinal center in the Fifth Army area. One hundred and eighty-three of these patients were studied roentgenologically by Captain S. M. Wyman, M.C., A.U.S. Among these 183 consecutive patients were x-rayed and gastroscopied to study the problem of gastritis, as well as to test the accuracy of the history alone in the diagnosis of peptic ulcer. The patients who were not x-rayed were diagnosed on the basis of the history and clinical observation.

At the Sixth General Hospital, where all patients were x-rayed, peptic ulcer constituted 8 per cent of the cases of chronic dyspepsia, as compared with 3 per cent at the gastrointestinal center of the Fifth Army. It would be expected that a higher percentage would be found at general hospitals because they receive patients already observed clinically in whom the suspicion of ulcer is therefore greater. The low incidence at the gastrointestinal center, where nearly all the patients were infantrymen who had engaged in heavy combat, is strong evidence that combat does not cause peptic ulcer.

The 8 per cent incidence of peptic ulcer among patients with chronic epigastric distress encountered in North Africa can be explained by the fact that this hospital, owing to its position, received more ulcer patients than did any other at the time. The experience of other general hospitals in the theater, however, is similar to ours in that far more ulcer patients were seen in North Africa than in Italy. It is probable that many more cases of the disease were not disclosed by the screening processes carried out in the Zone of the Interior earlier in the war.

CORRESPONDENCE

DIAGNOSIS OF DIABETIC COMA

To the Editor It is regrettable that, even though a specific remedy has been available for nearly a score of years, patients still die of diabetic coma. Since the subject is no longer clouded by theories, not only unsound but useless, such deaths are inexcusable.

Too few of my interns and residents have grasped the simplest concept of diabetic coma: it is a fatal sign of immediate danger from what is essentially a deficiency disease, an insufficiency of insulin not merely in the blood but in every cell in the body. Hence the primary factor in treatment is the degree of acidosis, whereas hyperglycemia and dehydration are but secondary, even incidental. Accordingly, instead of repeated blood-sugar examinations, tests for ketosis are obviously more reliable guides to the amount of insulin needed promptly and directly to restore the deficiency and thereby save the diabetic patient. Simple tests for urinary acetone and diacetic acid are usually preferable to determinations of the blood-sugar level.

NOTICES

ANNOUNCEMENTS

Dr Joseph S Barr, having returned from service with the United States Navy, has resumed practice at 234 Marlborough Street, Boston.

Dr Weston T Buddington, having returned from military service, announces the opening of his office for the practice of urology at 12 Bay State Road, Boston.

Dr S Forrest Martin announces the opening of his office at 101 Bay State Road, Boston, for the practice of ophthalmology.

Dr Channing S Swan announces his return to the private practice of urology with offices at 20 Gloucester Street, Boston 15.

GREATER BOSTON MEDICAL SOCIETY

A meeting of the Greater Boston Medical Society will be held in the auditorium of the Beth Israel Hospital on Tuesday, March 12, at 8 15 p.m. Dr Nathan Rosenthal, of the Mt Sinai Hospital, New York City, will speak on the subject "Blood Cell Reactions to Drugs." The paper will be discussed by Drs William Dameshek, Maxwell Finland, and Benjamin Alexander.

NEW ENGLAND HOSPITAL
FOR WOMEN AND CHILDREN

The monthly clinical conference and meeting of the staff of the New England Hospital for Women and Children will be held on Thursday, March 7, at 7 15 p.m. in the classroom of the Nurses' Residence. Dr Eliza A Melkon will speak on the subject "Allergic Manifestations after the Injection of Varicose Veins," which will be followed by a discussion by Dr Eda A Polcaro. Dr Dorothy K Scheidell will be chairman.

JOSEPH H PRATT DIAGNOSTIC HOSPITAL

Bennet Street, Boston

Lecture Hall, 9-10 a.m.

MEDICAL CONFERENCE PROGRAM

Friday, March 1 — Treatment of Psychiatric Problems
Case discussion Dr Mandel E Cohen
Wednesday, March 6 — Carcinoma of the Uterus Dr Louis E Phaneuf
Friday, March 8 — Streptomycin Dr Donald Anderson

Wednesday, March 13 — To be announced Dr Harold A. Abramson

Friday, March 15 — Clinicopathological Conference Dr Chester S Keefer and H F MacMahon

Wednesday, March 20 — Diagnostic Errors in the Pratt Hospital Dr C B Popplestone

Friday, March 22 — First Stages of Human Conception Dr John Rock

Wednesday, March 27 — Roentgenological Changes in Sprue and Other Nutritional Disturbances Dr Alice Ettinger

Friday, March 29 — Some Aspects of Military Orthopedics Applicable to Civilian Practice Dr Joseph S Barr

On Tuesday and Thursday mornings, Dr S J Thannhauser will give medical clinics on hospital cases. On Saturday mornings, clinics will be given by Dr William Dameshek. Medical rounds are conducted by some of our staff members from 12 00 to 1 00 in the Lecture Hall.

All exercises are open to the medical profession.

AMERICAN ASSOCIATION FOR THE
STUDY OF GOITER

The first postwar annual meeting of the American Association for the Study of Goiter will be held at the Drake Hotel, Chicago, on June 20, 21 and 22 — dates that are convenient for the majority of those planning to attend the meeting of the American Medical Association in San Francisco during the first week of July. Those who intend to be present at the Chicago meeting are advised to make their hotel reservations as early as possible.

SOCIETY MEETINGS AND CONFERENCES

CALENDAR OF BOSTON DISTRICT FOR THE WEEK BEGINNING
THURSDAY, MARCH 7

FRIDAY, MARCH 8

MAY 8 Annual meeting

dyspepsia, the mental reactions of the vast majority of the patients with peptic ulcer were strikingly different from those of the non-ulcer patients. Most of the latter were anxious to describe their symptoms in detail, whereas the ulcer patients were noncommittal and unconcerned with themselves, other than for the single definite symptom — pain. In other words, the symptomatology of the patient with psychogenic dyspepsia was a direct expression of his anxiety and insecurity, whereas that of the patient with ulcer had no direct connection with anxiety. In making ward rounds, it was noted that the ulcer patients rarely complained or volunteered information regarding the degree of pain unless direct questions were put. From these observations alone it has been possible to predict with a considerable degree of accuracy what x-ray examination will reveal in patients with chronic epigastric distress, regardless of whether the symptoms were typical or atypical of ulcer. In most cases it could be predicted that the x-ray film would be negative in those patients who were anxious and unduly concerned with their stomach symptoms. Only rarely was an ulcer diagnosed by x-ray when the clinical impression had been that the patient did not have an ulcer. Much oftener a clinical impression of ulcer was not substantiated by x-ray. This lack of anxiety in the ulcer patients is in contrast to the findings of Flood,⁹ who reports that 25 of 47 ulcer patients at the Station Hospital, Fort Meade, who had been studied neuropsychiatrically presented signs of anxiety. Schildkrout¹⁰ reports 23 per cent of 87 cases of duodenal ulcer studied at a staging area in the United States, as having a psychoneurosis.

The symptomatology of the patients in this series was considered typical of ulcer in 72 per cent of the cases, that is, there was a characteristic indefinable, dull pain in the epigastrium, coming on one or two hours after meals and often in the middle of the night, which was relieved by food. Vomiting was an infrequent symptom. The symptomatology of the non-ulcer patients, although often resembling that of the ulcer patients with atypical symptoms, was rarely typical of ulcer. In patients who had had an ulcer for but a short time, the symptoms as related by the patient were often atypical — much more frequently so than in those who had had the disease for a long time.

The family history was ascertained in 167 patients. In 74 (44 per cent) some member of the immediate family had had chronic digestive difficulties. A similarly high incidence of familial predisposition to chronic indigestion has been noted in all studies of peptic ulcer. Whether this tendency is the result of a constitutional predisposition or carries a psychologic implication is uncertain.

The physical examination was negative in the vast majority of cases except for moderate epi-

gastric tenderness, which was present in most cases. The x-ray examinations demonstrated a crater in 48 per cent of the cases so examined.

We were interested in the therapeutic response because of the lack of ideal facilities for treatment. Careful data could not be collected because the hospital stays before evacuation by transport to the Zone of the Interior were too short, being as a rule not more than two weeks. In the majority of cases, however, the degree of pain and discomfort was promptly lessened, usually within two or three days, and from then on the patients were quite comfortable.

The treatment instituted was the same in nearly all cases. Six-meal bland diets were provided, tincture of belladonna and alkaline powders being given as needed. The diet was limited in variety and not particularly palatable, owing to problems of supply. Feedings between meals consisted of powdered or evaporated milk, with or without crackers. Nearly all the patients were ambulatory. On admission, only 2 patients required complete bed rest with hourly feedings of milk. A few more were given for a few days two-hourly feedings of milk, with cereal, custard and crackers for the main meals. Tobacco was not prohibited. By and large, the symptoms of the entire series of patients were mild, responding promptly to the relatively crude dietary measures available. This finding is in contrast to Flood's⁹ observation that the patients studied at the Station Hospital, Fort Meade, responded poorly, both symptomatically and roentgenologically. Our patients responded to treatment much as one would expect in such cases in civilian practice. Flood considered that the factor of anxiety, occasioned or intensified by the rigidity of Army life and by uncertainty for the future, was responsible for the poor response to treatment in his series, which was chiefly composed of recent inductees. The 11 patients who had had long Army service, on the other hand, responded well to treatment except for 2 who were highly neurotic. The patients in our series had had full military training and had come to a theater of operations. As soon as the diagnosis had been established they were told that they were to be sent home, so that the anxiety factor was largely removed. Thus, the good response to treatment when the anxiety factor was minimal, in contrast to the poor response in a different series in which this factor was relatively strong, is confirmatory of the prevailing belief that psychogenic factors are of importance in peptic ulcer.

In contrast to the almost universally good symptomatic response of patients with peptic ulcer to dietary treatment and hospital care, patients with psychogenic dyspepsia rarely improved symptomatically as a result of these measures. This observation provides a valuable clinical test in differential diagnosis.

Because the functions of Army hospitals often differ and because the nature of the work of this hospital has changed from time to time, a comparison of statistics with those of other reports in the literature would not be contributory. It appears, however, that the figures from this hospital are roughly the same as those in other American and British reports⁴, as regards the incidence of gastroduodenal disorders as a whole in respect to total medical admissions. The British consistently report a far higher ratio of peptic ulcer to non-ulcer dyspepsia than is found in American reports. The reasons for this discrepancy are not clear. It is certainly true that chronic dyspepsia and peptic ulcer together form an important military medical problem, although in the Mediterranean Theater the former was much the more important of the two.

A study of chronic non-ulcer dyspepsia cases in this hospital has been made and reported elsewhere⁶. That study was primarily an investigation of psychiatric factors in etiology. It was found that in more than three fourths of the cases the cause was psychogenic, that is, definite psychogenic factors were present with no other organic explanation. In the remainder of the cases positive evidence of significant neurotic factors was lacking, although there was likewise no demonstrable organic cause. In cases with definite psychogenic factors the diagnostic term "psychogenic dyspepsia" was employed. Among a few of the remainder a later follow-up with subsequent study revealed that many of these cases were likewise psychogenic in origin. It was found that patients with psychogenic dyspepsia who had been long in hospitals could rarely be salvaged for further military service. It was further noted that the personality structure of a large majority of patients with chronic psychogenic dyspepsia was basically different from that of a large majority of patients with peptic ulcer.

METHOD OF STUDY

The large number of patients with peptic ulcer observed in a relatively short time forbade prolonged study, but data concerning the onset of the disease, with the possible influence on its course of various factors in the Army career, were accurately ascertained. Thus, in every patient the following data were noted: age, rank and branch of service, length of service, the duration of symptoms from the patient's earliest recollection of persistent indigestion (this was considered to be the onset of the disease), whether symptoms were aggravated on entrance into the Army, provided the disease had begun prior to induction, the date of departure for overseas service, whether symptoms had become aggravated coincident with overseas service (a period of time from two weeks before embarkation to four weeks after debarkation was arbitrarily chosen as the time of greatest nervous tension that might influence the symptomatology), and

whether the patient had been in combat and, if so, whether he had been wounded. In addition to these data, it was noted whether the symptoms were typical or atypical of peptic ulcer and whether there was a family history of ulcer or chronic indigestion.

In 100 patients, a detailed history was taken, attention being paid to factors of emotional or neurotic significance. Thus, all phases of the past history were investigated, including the family history and the educational, occupational, social, marital and military phases of the patient's life. These patients were interviewed by one of us (H W), a psychologist on the Neuropsychiatric Service, to make a further personality study. Both of us then discussed the findings that each had made independently. An average of two hours' time was spent on the history and personality study of each patient. The purpose of this investigation was to evaluate the nervous and emotional factors that might be present in the personality pattern of the ulcer patient and to compare them with the findings made in 100 patients with chronic non-ulcer dyspepsia who were being studied at the same time in a similar manner.

The laboratory studies included stool examinations and blood-cell counts when indicated, and occasionally gastric analysis. The latter test was considered to be of relatively little value in the diagnosis, treatment or prognosis of peptic ulcer, except in cases with gastric lesions, in which x-ray examination alone does not always enable one to differentiate ulcer and carcinoma and in which the presence or absence of free hydrochloric acid is significant. This viewpoint is in agreement with that of Schindler⁶ and Alvarez⁷ (but not with that of Chamberlin⁸), each of whom has recently discussed the value of the procedure in Army gastroenterology. The test was performed only in patients with gastric ulcer, in the few patients who did not readily respond to treatment and in 3 patients with duodenal ulcer in whom anacidity had been reported from other hospitals. Free acid was found in the last group when histamine was employed as a stimulant.

As previously noted, it was our policy to make x-ray studies on all patients with chronic epigastric distress. A few patients who had come from other general hospitals and whose records and clinical findings indicated entirely satisfactory evidence of an active ulcer were not again x-rayed. No patients were included in the series who did not have a constant deformity of the duodenum or a crater. In many questionable cases the examination was repeated two or three times. Spot films with compression technic were taken in nearly all cases.

CLINICAL ASPECTS

Clinical Findings

In the taking of histories of patients with chronic

these patients were promptly hospitalized and sent home, but the majority paid no attention to the symptoms, remaining on duty until the symptoms had become extremely severe and often engaging in combat without reporting to sick call. In 87 cases (44 per cent), the disease began after entry into the Army. In 50 of these (25 per cent), it began after the patient had started for or arrived in the Theater of Operations. Twenty-four of the 37 patients whose ulcers had begun after entry into the Army but before coming overseas reported that their symptoms became much worse shortly after starting for overseas service. Thus, of 150 patients who had peptic ulcer before going overseas, in 103 (69 per cent) an aggravation of symptoms or recurrence of the ulcer could be directly correlated with nervous tension.

The 150 patients who had peptic ulcer prior to embarkation should theoretically have been excluded from overseas service. The reason why they were not may lie in the fact that most ulcer patients observed in overseas areas are restless and aggressive, and frequently conceal or minimize symptoms in order to be accepted in the Army or to be sent overseas. Berk and Frediani¹⁶ state that their patients, who had not been overseas, did not conform to this type, that many were of low intelligence and that many made use of their ulcers to secure discharge from the Army. Thus, it may be that the ulcer patient who gets overseas is a different type of person in respect to aggressiveness.

Almost every patient's explanation of the recurrence or aggravation of his symptoms in the Theater of Operations was the difficulty of digesting the field rations on which he was obliged to subsist. That the accuracy of this is debatable is shown by the fact that the symptoms of many of these patients began or became aggravated at the port of embarkation or on the transport, and that when this occurred in the Theater of Operations it was not until they were subjected to the strain of air raids for the first time or started for the front, having been in the combat area and having eaten field rations for some time. This suggests that the main reason for the recurrence or aggravation of symptoms of peptic ulcer in these patients is not the type of food eaten but the nervous tension involved in overseas service.

DISPOSITION OF PATIENTS

The patient with peptic ulcer as seen in the Theater of Operations is a highly successful soldier who as a rule has had his symptoms for a considerable period of time without complaining to a medical officer. The disease is clinically mild, and there have been relatively few complications. These patients have been of much greater value to the Army than the dyspeptic patients without organic disease. Yet it has been the practice promptly to send home practically every ulcer patient, where-

as patients with non-ulcer dyspepsia are usually returned to duty or limited service, even though their disorder is generally more disabling and less amenable to treatment than peptic ulcer.

Patients with peptic ulcer in a theater of operations should in the large majority of cases be sent to the Zone of the Interior, because the chances of recurrence are extremely great and management of the disease outside a hospital is almost impossible. In this series, however, there were 6 patients in base organizations whose symptoms disappeared promptly and who were anxious to be returned to duty. After four to six weeks of hospitalization this was done. In view of the mildness of the disease as seen in this theater, the high military quality of most of the patients and the fact that in the United States nervous tension is lower and dietary conditions are better, it seems probable that many of the ulcer patients sent to the Zone of the Interior could be successfully utilized in a noncombat status within the United States after a few weeks of hospitalization.

PSYCHOSOMATIC FEATURES

In the foregoing sections certain statements regarding psychosomatic features have been made, inasmuch as they had an important bearing on the clinical aspects of the disease. These may be summarized as follows:

The extremely low incidence (3.4 per cent) of peptic ulcer among combat infantrymen hospitalized because of chronic dyspepsia is strong evidence that combat is not a factor in the cause of this disease. The reaction of patients with ulcer differed markedly from those with non-ulcer dyspepsia in that the latter were emotionally concerned with their stomach symptoms. Patients with a neurotic reaction rarely proved to have ulcer, even though the symptomatology resembled that of ulcer. Patients with peptic ulcer responded rapidly and satisfactorily to a crude dietary regimen. This differed from the response to treatment of a group in a station hospital in the Zone of the Interior, which may be interpreted as having been due to the patients' security in the knowledge that they were to be sent home. Lastly, there was a close correlation between aggravation of symptoms in a presumably active ulcer or recurrence of activity in a previously quiescent one, and the nervous tension associated with going overseas. Such a correlation was present in 103 of 150 patients.

It is believed by many workers that peptic ulcer is a psychosomatic disease in the sense that emotional disturbance with chronic nervous tension is an important factor, if not the primary one, in the etiology of the disease. No conclusive evidence can be drawn from the statistical data of this report in support of such a contention. Nearly 45 per cent of these patients developed ulcer after entry into the Army, and 25 per cent did so after coming

Type of Ulcer

There were 188 cases of duodenal ulcer (94 per cent) and 12 cases of gastric ulcer (6 per cent), the latter incidence being essentially the same as that reported by Flood⁹ and Annis¹¹ from two station hospitals in the United States. In the 12 cases of gastric ulcer (Table 1), the lesion was on the lesser

TABLE 1 Data on Cases of Gastric Ulcer (12 Cases)

CASE No.	AGE	RACE	LOCATION	DURATION	REMARKS
1	45	White	Lesser curvature	5 mo	
2	26	White	Prepyloric area	1 mo	Perforation
3	53	Negro	Prepyloric area	2 yr	Gastric resection possible malignancy
4	37	Negro	Lesser curvature	2 mo	
5	45	White	Lesser curvature	3 mo	
6	54	Negro	Prepyloric area	4 mo	
7	37	White	Antrum	8 mo	
8	24	Negro	Lesser curvature	1½ mo	
9	37	White	Lesser curvature	11 mo	
10	26	White	Prepyloric area	7 mo	Perforation
11	30	White	Prepyloric area	3 mo	
12	24	Negro	Lesser curvature	5 days	Subacute perforation (no operation)

curvature in 6 cases, in the prepyloric area in 5 — in 3 of which it was confirmed by operation — and in the antrum in 1 case. In 9 of the gastric ulcer cases the ulcer occurred after arrival overseas. These cases represented 18 per cent of the 50 cases in the entire series in which peptic ulcer developed after arrival overseas, as compared with 2 per cent of those in which disease had existed before going overseas.

Racial Distribution

There were 16 Negroes with peptic ulcer, or 8 per cent of the series. This is probably a normal incidence, taking into account the small proportion of Negro troops in this theater. It does not substantiate statements that have been made to the effect that Negroes are less prone than Whites to develop this disease. In 10 of the 16 Negroes (62 per cent), the onset occurred after arrival overseas. There were 5 cases of gastric ulcer among Negroes, or 42 per cent of the number of these ulcers in the series, a surprising and inexplicable percentage, considering that only 8 per cent of the 200 patients in the series were Negroes.

Age, Rank and Branch of Service

The ages of the patients were neither greater nor less than the average for the Army as a whole. One hundred and seventeen patients (59 per cent) had received at least one promotion. Seventy-two per cent of the patients belonged to combat branches of the Army. Fifty-four patients had engaged in a slight to moderate amount of combat, and 9 had been wounded, none severely.

Complications

As noted previously, all the patients in this series had been sent to this hospital from other hospitals,

where they had been treated initially. Because of this, there was only 1 case of major hemorrhage and 1 of subacute perforation. In the former case, the bleeding had begun on a transport from which the patient was transferred directly to this hospital, still bleeding moderately. A history of massive hemorrhage since arrival in this theater was obtained in 7 cases and one of perforation in 9 cases, the latter having been the first sign of the disease in 3 cases. Three of the cases of perforation were those of patients with gastric ulcer, and in 2 of these the perforation was in the prepyloric region, as verified at operation. The third patient, a Negro with an ulcer in the lesser curvature, was thought to have had a subacute perforation, since he had had severe pain at onset, with low fever and leukocytosis persisting for three weeks. He was not operated on.

It has been noted that the incidence of perforation in the civilian population of London during the two months of heaviest air raids in September and October, 1940, was three times as great as the normal average.¹² It has been thought that massive hemorrhage is especially frequent during periods of extreme nervous strain. The incidence of perforation and that of hemorrhage in this series — 4.5 and 3.5 per cent respectively — are not high, being essentially the same as those reported by Thomas¹³ among 75 cases from Fort Meade. If psychogenic factors are important as precipitating causes for these complications, as suggested by Stewart and Winsor,¹² the low incidence in this series may be due to the fact that the military population was composed of trained, disciplined soldiers.

Pyloric obstruction occurred in 3 patients, 2 of whom required gastric resection before they could be sent home.

Onset of Disease in Relation to Army Service

Reports in the literature on soldiers with ulcer studied in the United States agree that in 90 per cent the ulcers occurred prior to entry into the Army.^{9, 14} This is in accordance with British figures.¹⁵ According to Chamberlin,¹⁴ these patients reach the hospital on an average of five months after induction. Ninety-three per cent of Flood's patients, who were recent inductees, had had symptoms prior to induction. Essentially all this group were discharged from the Army. The results of our inquiry into the onset of the disease in relation to time of entry into the Army are quite different.

In 113 patients (57 per cent) there was a history of unexplained indigestion or symptoms resembling those of peptic ulcer prior to entry into the Army. In 33 of these patients, a recurrence or aggravation of symptoms occurred within four weeks after entry into the Army, but not many of them sought medical attention. In 79 cases, recurrence or aggravation occurred shortly after arrival overseas. A few of

have been so striking as to leave no doubt that they actually exist. The main personality features that have been described were surprisingly uniform and definite. In the regimented life of the Army, when all men live exactly alike, exposed to the same difficulties and the same needs for adjustment, and where the opportunities for compromise existing in civilian life are lacking, the differences are doubtless far more obvious than they would be in civilian practice. Additional studies of patients of the latter sort, both men and women, are needed to confirm or disprove the conclusion drawn from this study of men living under regimented conditions, to the effect that those who develop peptic ulcers have a personality pattern fundamentally different from that of those who develop psychogenic dyspepsia.

If one accepts the hypothesis that psychogenic factors are important in the etiology of peptic ulcer, it is illogical to assume that psychogenic dyspepsia, in which the personality type differs markedly from that in peptic ulcer, should develop into the latter. Schildkrout¹⁰ and Urquhart¹⁹ have commented on the low incidence of functional dyspepsias that later develop ulcer, the latter finding it to be less than 3 per cent. If such did occur, one would expect combat infantrymen to develop the disease in large numbers, inasmuch as psychogenic dyspepsia is extremely frequent among them,¹⁷ yet it is extremely rare.

On the other hand, that peptic ulcer is a psychosomatic disease is not yet proved. The above data, both statistical and psychiatric, are consistent with such a theory, yet add no conclusive supporting evidence. The discrepancy between our findings and those of Flood,⁹ Berk and Frediani¹⁶ and Schildkrout¹⁰ on soldiers with ulcer in the United States as regards personality factors and response to treatment has several possible explanations, among which are the following. Standards of psychiatric evaluation, always largely subjective, may have differed. Environmental factors are known to affect the form of any psychologic reaction. For example, severely wounded soldiers react quite differently to pain from civilians with comparable injuries. Finally, it may be that the man with pre-existing ulcer who manages to get overseas is actually a more aggressive, effective soldier than those who remain in the United States.

It is hoped that the observations reported herein may be of use in integrating the many factors involved in the psychosomatic aspects of peptic ulcer. Much further work will be required before a psychogenic factor can be assigned a specific major role in the etiology of this disease.

SUMMARY AND CONCLUSIONS

A clinical study has been made of 200 consecutive cases of peptic ulcer seen in a general hospital in the Mediterranean Theater of Operations. The

disease was mild, and the response to treatment was prompt and satisfactory, being similar to or more favorable than that observed in civilian practice. The incidence of major complications was no higher than that noted among soldiers in the United States.

A study of psychosomatic features revealed that distinct episodes of nervous stress could be correlated with an aggravation of symptoms or recurrence of previously existing ulcer in 69 per cent of 150 patients whose disease had begun before coming overseas. Only 3.4 per cent of 183 combat infantrymen with chronic epigastric distress had peptic ulcer. The disease was more frequent among base troops than among combat troops.

Forty-four per cent of the patients developed the disease after entry into the Army, and 25 per cent developed it after beginning overseas duty. Reasons are given for believing that these figures are not significant as indications that the nervous tension of Army life is a direct factor in etiology of new ulcers.

The results of a psychiatric study of 100 patients were consistent with those of previously reported work on the personality pattern of patients with peptic ulcer. This pattern was markedly different from that of the large majority of patients with psychogenic dyspepsia, and is valuable as a differential point between the two disorders.

Reasons are given for believing that psychogenic dyspepsia does not evolve into peptic ulcer.

overseas This is in contrast to reports from Army hospitals in the United States, where 90 to 95 per cent of patients with ulcer had had the disease prior to entry into the Army, and suggests that the nervous tension of Army life is at least a contributory cause of the disease This difference may, however, be explained otherwise The incidence of the disease is normally highest in men of military age With the screening out of a large number of men with old ulcers in the United States before their units were sent overseas, the percentage of new ulcers that would normally be expected to develop in this age group should be higher in men who have been sent overseas because they have been longer in the Army

Subsequent information obtained at the end of the war in Europe revealed that the incidence of peptic ulcer in the entire Mediterranean Theater of Operations was low, and probably lower than the expected incidence for men of military age

New peptic ulcers were rare among infantrymen exposed in Italy to part of the most intense and difficult combat of the war This indicates that fear, with the associated nervous tension, is not a factor in the etiology New ulcers were seen more frequently among base troops than among combat troops, and this suggests that the frustration of regimentation with frequent periods of inactivity may be more damaging than actual danger, in which there are opportunities for release of energy through aggressive action

It was to study the psychiatric features of patients with peptic ulcer that the personality study of 100 patients, described above, was made From a psychiatric viewpoint, the study was a superficial one, since many hours with each patient would have been required to make an accurate and deep survey Nevertheless, as a result of both the interviews and the observations of the patient's reactions made on daily ward rounds, it was possible to determine whether the patient was neurotic, to obtain data regarding his past environment and to get a clear picture, at least on a superficial level, of his characteristic personality pattern This could be contrasted with that of the patient with psychogenic dyspepsia The marked differences noted have proved to be of practical value in differential diagnosis Many patients with psychogenic dyspepsia have no apparent anxiety, their only complaint being epigastric distress In the Army, hospitalization of such patients is harmful, inasmuch as symptoms grow more fixed the longer they are studied and treated from a medical rather than a psychiatric standpoint Early diagnosis and disposition from medical channels at forward hospitals, in many of which x-ray facilities are not available, has been shown to be of marked military value, as well as of definite therapeutic value, in such patients¹⁷

Data regarding the background of the patients

with peptic ulcer revealed two important features suggestive of emotional insecurity Thirty-nine per cent of the patients had had an unfavorable childhood environment, such as separated or incompatible parents or severe economic distress resulting in neglect Nineteen of 49 patients who had married were divorced or separated Other factors that could be analyzed statistically were perhaps no more prominent than those to be found in any random group of men Thus, 13 per cent of the patients had had enuresis in childhood, 20 per cent gave a history of anxiety phobias, such as fear of high places, of the sight of blood or of accidents, 20 per cent drank somewhat excessively on occasion, and 19 per cent had mild or moderate psychosexual conflicts

Despite the presence of neurotic factors in a considerable proportion of the patients, only 5 per cent demonstrated a clinical neurosis In other words, the large majority were not disabled by whatever neurotic traits were present The patients with neuroses were abnormally concerned with their gastric symptoms, which seemed to have emotional value for them, and also showed evidence of anxiety More extensive investigation would perhaps have disclosed in a larger number of patients significant neurotic features of an aggressive type with overcompensation This has been demonstrated by Mittelman, Wolff and Scharf¹⁸

It has often been stated that the patient with peptic ulcer tends to be an unrelaxed, hard-driving, overaggressive person We have noted this to be true as a general trend among our patients In spite of a surface appearance of self-sufficiency, the characteristic ulcer patient, as we have observed him, is not relaxed and is not free of anxiety, as has been noted by other writers He is not normal in his behavior and feelings, although his abnormal temperament leads to material success This generalization is based on the fact that most of these patients when asked if they often felt nervous complained of being restless and unable to relax The behavior on the ward of the large majority of patients was one of restlessness and impatience, thus confirming this statement The ulcer patient, however, seems to solve his underlying insecurity differently from the patient with psychogenic dyspepsia In contrast to the latter, he has developed an abnormal drive combined with restlessness and impatience, by which he controls his anxiety The dyspeptic patient magnifies his every illness and is overcome by it, whereas the ulcer patient shows an apparent indifference to the whole affair Our ulcer patients conformed to the description given by Mittelman, Wolff and Scharf,¹⁸ whose patients showed assertive independence and self-sufficiency, covering underlying anxiety and insecurity and accompanied by feelings of resentment and hostility

These differences between the two groups, although gained from a superficial personality study,

fects in this initial surgery. We have been impressed by the speed with which these wounds first come to débridement and by the excellent work done by the evacuation hospitals. Sometimes, of course, through force of circumstances, delay is unavoidable and débridement is incompletely done. This is always apparent in the condition of the wound and necessitates the placing of preliminary wet dressings before closure can be attempted. Bits of foreign material have sometimes been found in such wounds when it was obvious that the pressure of casualties had allowed less careful treatment. The desirability of adequate débridement needs no emphasis to the tireless workers who have done such perfect work in the advance units. Testimony of the effectiveness of their work is furnished by the fact that a large percentage of wounds reached us in such perfect condition as to permit immediate closure.

Intermediate Dressings

Most patients consider that a surgical dressing is evidence of careful medical attention. That wounds should be débrided and dressed seems reasonable to the layman. A white gauze bandage quickly becomes soiled, is frequently loosened and is usually blood stained. To remove this unsightly dressing and apply a clean, firm, fresh one pleases most patients and too many physicians. That every change of dressing, even under the most favorable conditions and with the best aseptic technic, means introduction of infection is a fact not sufficiently recognized, and when the conditions are not so ideal and the technic not so scrupulous, the danger is considerably increased. One needs only to observe the contrast in the clinical appearance of wounds coming to a general hospital to appreciate this fact. The ideal wound for closure is the one which has its débridement dressing removed in the operating room just before suture. Most wounds associated with fractures and therefore encased in plaster casts, which effectively discourage intermediate dressings, are cleaner than simple flesh injuries, even though they are generally much more extensive. Perhaps all débrided wounds should be dressed with a light plaster, which would afford greater protection to the damaged tissues and be more resistant to soiling and disarrangement, and thus less likely to invite a change of dressing. Certainly intermediate dressings should be discouraged unless there is a definite indication for them, such as fresh bleeding or systemic evidence of infection.

Chemotherapy

All patients received through American installations had already received chemotherapy in some form. Penicillin has been given routinely for forty-eight hours after closure, but not after that time except for specific indications. The excellent condi-

tion in which the ideally treated wound is found is considered in some measure due to previous chemotherapy. Certainly when one sees extensive abdominal wounds and patients with multiple compound fractures, the wonder frequently is that they have survived long enough to reach a general hospital. There can be little doubt that many of these patients owe their lives to early chemotherapy. Once they have reached this hospital, an adequate defense mechanism has been established, and only enough penicillin is needed to tide them over whatever breakdown of the walling-off process is incident to the secondary closure.

Method of Closure

As indicated above, we prefer to book candidates for secondary closure without prior inspection and to have the dressing initially removed on the operating table. On removal of the vaseline gauze with which the wound should be loosely packed, the tissue should be beefy red, with no foreign material and no suppuration or slough. The skin borders should be pliable and elastic, with no surrounding induration or inflammatory reaction. Usually the general appearance of the wound invites closure. Some wounds have a mild grayish exudate with a slightly glistening sheen, which has not been found to be a danger signal. We do not apply antiseptics to the area or even wash out the wound itself. The wound is covered with a sterile sponge while the surrounding skin area is being prepared. In most cases preparation consists of painting the wound with two coats of Tincture of Merthiolate and one of alcohol. If the dressing has been disarranged and the area around the wound thus contaminated, it is cleaned with a sponge moistened with tincture of green soap or ether before applying the antiseptic solutions. It is thought that too vigorous scrubbing of the area may wash bacteria into the wound, so that the skin is washed at this time only when such a step is visibly indicated. The wound itself is not prepared in any way. The presence of a little vaseline does not interfere with the healing of closures or with grafting procedures.

It takes some experience to judge whether a wound is of suitable size and shape for direct closure. With more experience, it will probably be possible to apply this procedure to seemingly hopeless cases. It has been found that even considerable tension is tolerated if other conditions are favorable. Looseness of the skin is a distinct advantage. Wounds of the back, chest, abdomen and thighs are more easily closed than are much smaller ones on the forearm or lower leg. Special caution has been observed in dealing with wounds of the buttocks, and in many cases it has been considered best to strap them with fenestrated adhesive strips. This method in fact produces almost as good a closure as does suturing, and it is preferable when there is any possibility of sepsis. It has the advantage of

THE RESULTS OF SECONDARY CLOSURE

LIEUTENANT COLONEL PHILIP S. FOISIE, M.C., A.U.S.*

IT HAS been observed that the victory in World War II is likely to be credited to penicillin and secondary closures. The humor of this remark detracts in no way from the importance attached to these surgical aids by those who have witnessed their proper application.

During the last nine months we have done secondary closures on 1450 patients, these closures constituting 43 per cent of all operative procedures. Since many of these patients had multiple wounds, as many as thirty wounds having been closed in a single case, the total number of wounds closed is well over two thousand. It would be meaningless to give over-all percentages of results regardless of the antecedent histories, since this would combine the favorable cases having a normal expectancy with those presenting little hope of success, and thus give a true picture of neither group. Because of the vicissitudes of the process of evacuation, patients have arrived with every conceivable type of wounds — early and late ones, those not touched since their débridement and those frequently dressed, wounds with accompanying trauma to blood vessels, nerves, tendons and bone, and wounds of all sizes and shapes and in all locations. As regards cases with extensive loss of tissue and exposure of important structures, the choice of the appropriate plastic procedure requires discussion in specialized articles, but the ordinary flesh wound needs primary consideration because the basic principles of its treatment apply in almost all war injuries.

Our introduction to battle casualties gave us a mixed group of cases many of which were too old for successful closure. These received wet dressings and many of them were finally closed, but we seldom obtained better results than an indurated scar having wide suture marks and causing difficulty in mobilizing the adjacent joints. It was obvious that once a wound became infected the end result would be impaired even though the wound were properly cleaned before closure. It was equally obvious that open wounds would become infected even with careful dressings. The logical answer seemed to be to close the wound at the first dressing after débridement. It has been our policy to do this whenever possible, and experience indicates that it gives the best results.

After the first convoys mentioned above had arrived, we received patients evacuated by air, many of whom had wounds that were only two or three days old. These cases were scheduled for

operation without even preliminary ward inspection. This policy caused a few "dry runs," but it was believed that the advantage gained in the large majority of cases warranted this inconvenience. There were occasional small wounds that did not require closure — cases with perforating small-arms wounds in which it was not desirable to seal up a long tract and with odd septic wounds. Cases with a favorable history, that is, one of adequate and prompt débridement and no intervening dressings, amounted to no more than 5 to 8 per cent of the total.

As the battle front got farther away, cases as old as three or four weeks again began to arrive. These had usually been dressed many times, and the incidence of infection was so high that it was no longer permissible to close them immediately, and it was necessary to revert to preliminary wet dressings, with a corresponding worsening of end results. The evacuation pendulum finally again swung in our favor, and recent convoys have brought in patients with wounds four, five and six days old. Once more the operating rooms were kept going at full speed so that all these wounds could be closed at the first dressing. The results were satisfactory.

This varying experience has shown that the results of secondary closures can be quite accurately predicted on the basis of the conditions under which the operation is performed. With a prompt and adequate débridement and no intervening dressings, wounds that are closed by the end of the first week have healed without complications in 95 per cent of cases. In less than 2 per cent of such cases frank sepsis has been encountered. Only 3 per cent have developed hematomas that had to be evacuated. Moreover, these wounds heal with a minimum of induration and inflammatory reaction. After ten days, as the number of intervening dressings and the time interval between them increase, there is a corresponding decrease in the percentage of wounds that can be closed at the first dressing, reaching zero in about three weeks. In the cases of this group and those that are closed after being cleaned, a percentage of satisfactory results of 60 per cent is the highest that can be expected. Here one encounters much more drainage, breaking down of all or a portion of the wound and considerable inflammatory reaction, cutting in of sutures and finally greater scar contracture.

Débridement

The value of prompt and complete débridement is easily seen at the time of attempted closure. The pressure of action at the front is quickly re-

*Assistant to visiting surgeon, Boston City Hospital; instructor in surgery, Tufts College Medical School (on leave of absence).

study medicine. They were eventually assigned to civilian hospitals or trained as specialists. It was evident that the various professors did not desire women as their assistants or as students for prolonged training leading to eventual certification in a specialty.

Thus, the main difference in the selection of students, as compared with the prewar method, was that the majority were admitted by appointment from an outside authority. There was no apparent screening by an entrance board, and many students who had a natural aptitude and desire for the study of medicine never had the opportunity to enter medical school.

Undergraduate Training

Without question, the war drastically interfered with the training of medical students. In the first place, the total length of study — premedical and medical — was decreased from six years, or twelve semesters, to five years, or ten semesters. Finally, early in 1945 it was further reduced to four and a half years, or nine semesters. Since the majority of the students were under control of the Army, they had many interruptions associated with military training and Nazi Party functions. At least one semester of the premedical years was spent by the student as a medical corpsman at the front. During the three medical years he had to spend approximately two semesters working in an Army hospital at the front. Probably the students with considerable previous military service were excused from some of these assignments. There seemed to be no systematic arrangement for the assignment of these students to Army service for any given period of time. Apparently, groups were sent throughout the year for periods ranging from a few weeks to three months. Ordinarily, in the years of clinical study they would have worked for a period of three months in each of the various clinics, such as those of surgery, medicine and otolaryngology. As a result of this Army service, many must have missed the opportunity for bedside teaching and clinical work in hospitals other than that afforded at the front. Certainly, no faculty under the circumstances could have juggled a curriculum to cover the needs of such a fluctuating student body. The total time actually spent in the university, including the premedical and medical terms, was in reality limited in the majority of cases to about three and a half years.

The effect of the above-mentioned factors alone was sufficient to produce a drastic lowering in the quality of medical graduates. There were, however, other serious influences, which were brought out by all the professors. They emphasized the effects of the general hardships of a prolonged war and the attitude naturally associated with war as distracting even the better students from serious study and application. Education had been further interfered with, especially during the previous

eighteen months, by air-raid alerts and the destruction of buildings by bombing, with consequent overcrowding in other buildings. For example, although lectures were begun at 8 a m, by 10 a m there was usually an air-raid alert, which compelled students to enter shelters and remain there until noon. Frequently there was another alert at about 2 p m, evening study was interrupted by alerts, and sleep was constantly broken by alerts that came at about 2 00 a m. As a result of aerial warfare, not only was study and sleep interfered with, but only about half the time was it possible to attend classes. As the result of bombing of buildings, one of the professors of surgery had as many as 250 students in one class. Since the number of assistants decreased by one half and since the civilian patient load was quite heavy, it was impossible for the teachers to instruct the students as thoroughly as had been possible in peacetime.

Postgraduate Training

In peacetime, the professors of medicine and surgery had approximately twenty to forty assistants, depending on the size of their clinics, but during the war the number was reduced by at least half. Assistants were appointed from a group of promising students who applied to the professor of their choice for postgraduate training in some specialty. If the applicant was an able-bodied man, he had to be deferred by the Army as nonessential and in addition had to be cleared by the Ministry of Education. The number of men available was so limited that it was necessary for the professors to accept an increasing number of women as assistants each year.

Assistants were paid from 5000 to 7000 marks yearly, depending on the length of service. At least one of them was used in the private clinic of the professor concerned for one year. Occasionally the professor would arrange for the assistant to increase his income by caring for semiprivate patients in the clinic and by filling out insurance reports and other papers. Health insurance appeared to be quite popular with the teaching staff.

In surgery, at least, a minimum of four years was required before the professor issued a certificate attesting that the assistant was qualified in his specialty. Assistants showing particular ability in teaching and research might be retained for as long as ten years. They were given more responsibility each year and were finally qualified for teaching appointments in the universities.

In peacetime and early in the war, at least two Army officers were sent to each clinic for further study in surgery and medicine. Before the end of the war the number of Army doctors sent and the time spent in the various clinics were variable. These men were assigned by the Army, and the number and type of students were no longer controlled by the professors.

not sealing the wound and of pushing rather than pulling its edges together. It gives better results with deep wounds than with shallow ones, in which it has a tendency to roll the edges inward. An extensive wound that laid the buttock open down to the sciatic notch and extended from the sacrum to the thigh was closed with wide adhesive "butter-fly" straps, with excellent healing and a completely satisfactory scar.

Closure has been accomplished largely with deep interrupted silk sutures, the bottom of the wound being picked up to obliterate dead space. Only rarely have buried sutures been used. If it is considered necessary to close the fascia of the thigh with buried catgut, a Penrose drain is inserted under the fascia and carried out through the most dependent portion. The drain is removed in forty-eight hours. If necessary, the skin margins are unhesitatingly freed to facilitate approximation.

If the size, shape or location of the wound prohibits direct closure, some type of grafting is indicated. The indications and technic for these procedures require special consideration and will not be discussed herein, but the principle of early closure at

the time of the first dressing applies equally well to plastic procedures. In other words, the wound should be closed at the optimum time by whatever method is necessary—simple closure if feasible, a split-thickness graft if the difficulty is just a question of too much skin loss, or a pedicle graft for gouged-out wounds exposing vital structures. In some wounds a combination of all three methods is required.

* * *

Whatever the method of closure, it never has so favorable a chance of success as when done at the first dressing by the end of the first week. Complete epithelialization at this time affords the best possible dressing, lessens the incidence of infection, obviates painful dressings, conserves material and reduces nursing care and, most important, improves the chances for a good functional result. The goal of the evacuation system should be to get these patients to a hospital in which their wounds can be closed by the end of the first week. Intermediate dressings en route should be discouraged unless they are absolutely necessary.

MEDICAL EDUCATION AND PRACTICE IN GERMANY DURING THE WAR

COLONEL ROBERT M. ZOLLINGER, M.C., A.U.S.

INFORMATION concerning medical education and practice in Germany has been scanty during World War II. Because of the past achievements of German medicine it was considered important, both for the present and for the future, to attempt to evaluate its status during the last five secretive years. Certainly the standards of medical and surgical care of the German soldier at the front were not impressive. Only after the defeat of his country was it possible to visit the medical centers responsible for the education of the German medical profession. The following recent impressions were gained after visiting the clinics of the professors of medicine and surgery in three prominent German medical schools.

MEDICAL EDUCATION

Source of Students

The quality of any professional school is founded not only on the educational and research facilities offered but also on the caliber of the students themselves. All the professors of the medical schools visited agreed that the caliber of the students was far below the prewar level. They recognized this as an alarming situation and believed that it was due to the following factors:

The majority of the students came directly from the Army, and in many instances they had been actuated only by a desire to avoid the hardships and dangers of combat. Consequently, they had ex-

pressed a desire to study medicine and had therefore been released by the Army for such study. In most cases they had neither the background nor the aptitude for study in a medical school. The students in this group consisted of physically fit men who were part of the so-called "Student Combatant Corps." They were under the direction of an Army officer in each school. They wore uniforms and were committed to the Army while at school and at the end of their studies. Their tuition was apparently paid by the State.

A smaller group consisted of soldiers discharged from the services because of general physical disability or for various other reasons. The State paid for their education and directed their assignment to a civilian or static military hospital after the completion of their education.

Another group consisted of those initially unfit for military service and of a few who had been excused from it because they had demonstrated a particular aptitude for the study of medicine. These students paid their own tuition, which amounted to 300 to 400 marks yearly, and their living expenses, which approximated 120 marks monthly. After completion of their studies, they were assigned to civilian or static military hospitals. A select few were trained as specialists following graduation.

The last group consisted of an increasing number of women who were admitted to the universities to

It was mentioned by a certain surgeon that one of the greatest advances in neurosurgery was the primary closure of compound wounds of the brain. Apparently primary suture of severed nerves at the time of injury was not practiced, but there was an attempt at loose approximation with one or more silk guide sutures. Secondary suture for injuries of the radial and ulnar nerves below the elbow was done four months after injury; that for nerve injuries above the elbow six months after injury, and that for division of the sciatic nerve eight months after injury. Early anastomosis of the nerve was not practiced, although it was generally agreed that better results might be obtained if early suture were attempted and if neurolysis were carried out more frequently.

The treatment of chest wounds was neither standardized nor modern in its concepts. Foreign bodies with rough edges larger than 1.5 cm in diameter were sometimes removed. Smooth asymptomatic foreign bodies were not removed unless there was associated hemorrhage, abscess or pain. Hemothorax was treated by occasional aspirations during the first four weeks, but no attempt was made to keep the pleural spaces completely dry. Decortication of the lung was not generally practiced, and it is probable that the indications for this operation were not understood. Empyemas were treated with constant suction for approximately three weeks through a No. 16 catheter; irrigations were not utilized during this period.

So far as could be determined, there were no new principles governing abdominal surgery; colostomies were not routinely performed for injuries to the large bowel. Sulfonamides were not applied within the intraperitoneal cavity unless there was evidence of established infection, but under such circumstances there was no hesitation in introducing as much as 20 gm of the drug.

Some attempts had been made to perform blood-vessel anastomosis, with fine silk as suture material. Heparin was apparently not available, and no special technics for anastomosis were developed. Occasionally the femoral vein was ligated as a prophylactic measure in the presence of pulmonary infarcts.

Extremely few early cases of trench foot had been treated in the civilian clinics visited. Those in charge were primarily concerned with the late complications, and invariably recommended paravertebral block of the lower two or three lumbar sympathetic ganglions, 10 cc. of 0.75 per cent novocain being used in each site. For troublesome causalgia, 1 cc of 70 per cent alcohol was injected in the vicinity of the appropriate ganglion after the preliminary injection of novocain.

The surgeons used vitamin preparations, but did not have so much confidence in this form of therapy as did the internists. Information was volunteered that children with infections who had been treated

in relatively dark bombproof hospital pregnancy on as six months and had got little sunlight do about as well as did those treated to a high hospitals where plenty of sunshine was a lowering Vitamin K did not seem to be used extensively at all. Patients with intense jaundice were with calcium and blood transfusions.

There was no evidence of the use of plasma type of amino-acid preparations for the intravenous therapy of malnutrition. 1928
ref. in

Although there was general agreement that widespread use of whole-blood transfusion constituted one of the major advances of the war, there was little evidence that the actual requirements of whole blood in the various surgical conditions were understood. Transfusion was largely effected by an antiquated direct method, although occasionally the citrate method was employed, neither glucose nor refrigeration seemed to have been in use as a preservative in civilian hospitals. Each city had a list of donors, usually workers in large nearby factories, so that whole blood was readily available. The donors were paid 25 marks for each transfusion (500 cc), and in addition were given extra coupons for food rations; these incentives were sufficient to ensure an adequate supply of donors at all times. Wet plasma was available, but neither the dosage of blood nor that of plasma appeared to be controlled by laboratory tests or to be based on previous scientific estimations of the requirements for any particular type of case. No information concerning the use of plasma substitutes was obtained.

The operating rooms in the various clinics did not contain a single modern anesthesia machine. It may be that some of these machines had been sent to the Army or stored outside the city for protection against bombing. It could not be determined, however, that the surgeons employed gas anesthesia, and they seem to have had little experience with intratracheal anesthesia. They used 0.5 to 1.0 per cent novocain for local anesthesia in many operations, and barbiturates were widely employed intravenously. Ether was used for inhalation anesthesia except in cases presenting pulmonary infection, in which chloroform was used. There was little mention of spinal anesthesia, which was certainly not used in surgery of the upper abdomen. Morphine, pantopon, dilaudid and scopolamine were utilized in various combinations.

No new instruments or modern devices were observed in any of the clinics visited. Some of the surgeons, however, were enthusiastic about the use of long metal rods that were introduced into the medullary canal in the treatment of fractures of the long bones, especially those of the femur. They did not employ scalpels with detachable blades. Sewing clamps of the von Petz type were available for gastric and intestinal surgery. In most clinics an electrocoagulation and a cutting unit were available. Casual observation tended to confirm the

Research

It was evident that there was little opportunity for research, and as a result few significant contributions in this field were made during the war. Although the various professors appeared to be of high caliber, and had in the past carried out or supervised extensive research projects, this activity during the war was greatly curtailed by many factors. In the first place, as already mentioned, the number of assistants was decreased by half. The students were of such poor quality that few had either the time or the inclination to assist in research projects. In some instances the professors had served for long periods as consultants in the Army. On their return to civilian life they were burdened with a tremendous professional load of civilian patients and casualties from air raids. In some cases extensive damage had been done to the clinics and laboratories, which further impeded research. In some clinics all the surgery had been performed during the past eighteen months in bomb-proof, partially underground hospitals of limited space. There was also an understandable shortage of drugs and supplies for patients, let alone research projects. The majority of professors, however, attempted to continue their investigations pertaining to subjects that had interested them for years, but many times they were unable to publish their findings or to have reprints of their articles made because of the paper shortage, or because of arbitrary discriminations of one kind or another made by Nazi officials. Apparently the latter were especially active in curtailing the publication of articles pertaining to a medicohistorical subject.

It is fair to say that individually the professors expressed resentment of the occasional appointment by the Nazis of inferior men to head departments, although such interference was apparently limited to certain universities. Furthermore, they appreciated keenly the loss to the universities in the last few years of some men as a result of racial discrimination. Inquiry was made of each professor regarding what he considered to be the greatest advance made during the war, invariably the answer was, "The use of sulfonamides." Second in importance was the rather widespread use of whole-blood transfusion. Penicillin had never been made available.

MEDICAL PRACTICE

Surgery

Specific inquiry was made concerning the principles of therapy utilized for some of the more frequent general surgical conditions. The various specialties were not evaluated. Although the basic principles of good surgery appeared to be thoroughly understood, it was evident that many practices were years behind the times. Although the individual clinics may have standardized their procedures, there was little evidence given by the men

who had served as senior consultants in the Army that a systematic routine for the management of battle casualties was practiced.

Sulfonamide therapy was considered the greatest advance of the war, and many different varieties of the drug, comparable to those available in the United States, were utilized. Although enthusiastic, the surgeons did not have so much confidence in the sulfonamides as did the internists. Certainly, in two of the large clinics they were not sure of the value of sulfonamides when applied locally in open wounds. Apparently both in civilian practice and in the Army it was optional with the surgeon whether sulfonamides were dusted into wounds. They all emphasized that adequate surgery was more important than chemotherapy. Sulfonamides were used in the treatment of gas gangrene, but the surgeons had no confidence in their effectiveness.

All wounds were débrided if seen within forty-eight hours after the time of injury, and the majority were left open. The value of early secondary closure for most wounds was not appreciated. A few large wounds were secondarily closed from five to seven days after débridement, but this was not a routine procedure in either civilian or Army practice.

Gas-gangrene antitoxin was used in the Army for wounds in susceptible areas, such as those of the upper thigh. There was general agreement that adequate radical surgery was the only efficient method of preventing gas gangrene, as well as of treating it after infection had developed. Little confidence was expressed in gas-gangrene antitoxin or the sulfonamide drugs in the management of such cases.

Relatively little tetanus was seen in civilian practice, although there had been a noted increase during the last six months. There was a tendency to attribute this to the fact that the recently manufactured antitoxin was probably defective. Tetanus antitoxin seems to have been given to all wounded men, and tetanus toxoid was reserved for special troops. Once tetanus had developed, it was treated by the daily injection of antitoxin, either intravenously or intrathecally. Avertin was used to control muscle spasm.

The treatment of burns appeared to be fairly standardized in the several clinics visited. In most of them the wound was débrided by brushing and by the application of alcohol under general anesthesia. Following this, a powder, whose active principle was tannin, was applied and the area was covered with dry gauze. In some cases boric acid and vaseline — and in others cod-liver oil — were applied to the burned areas. There was a tendency to give whole-blood transfusions daily, plasma was given only as a substitute. Pressure dressings, immobilization, early skin grafting and the requirements of blood and plasma replacement were not appreciated.

It was mentioned by a certain surgeon that one of the greatest advances in neurosurgery was the primary closure of compound wounds of the brain. Apparently primary suture of severed nerves at the time of injury was not practiced, but there was an attempt at loose approximation with one or more silk guide sutures. Secondary suture for injuries of the radial and ulnar nerves below the elbow was done four months after injury, that for nerve injuries above the elbow six months after injury, and that for division of the sciatic nerve eight months after injury. Early anastomosis of the nerve was not practiced, although it was generally agreed that better results might be obtained if early suture were attempted and if neurolysis were carried out more frequently.

The treatment of chest wounds was neither standardized nor modern in its concepts. Foreign bodies with rough edges larger than 1.5 cm in diameter were sometimes removed. Smooth asymptomatic foreign bodies were not removed unless there was associated hemorrhage, abscess or pain. Hemothorax was treated by occasional aspirations during the first four weeks, but no attempt was made to keep the pleural spaces completely dry. Decortication of the lung was not generally practiced, and it is probable that the indications for this operation were not understood. Empyemas were treated with constant suction for approximately three weeks through a No. 16 catheter, irrigations were not utilized during this period.

So far as could be determined, there were no new principles governing abdominal surgery, colostomies were not routinely performed for injuries to the large bowel. Sulfonamides were not applied within the intraperitoneal cavity unless there was evidence of established infection, but under such circumstances there was no hesitation in introducing as much as 20 gm. of the drug.

Some attempts had been made to perform blood-vessel anastomosis, with fine silk as suture material. Heparin was apparently not available, and no special technics for anastomosis were developed. Occasionally the femoral vein was ligated as a prophylactic measure in the presence of pulmonary infarcts.

Extremely few early cases of trench foot had been treated in the civilian clinics visited. Those in charge were primarily concerned with the late complications, and invariably recommended paravertebral block of the lower two or three lumbar sympathetic ganglia, 10 cc. of 0.75 per cent novocain being used in each site. For troublesome causalgia, 1 cc. of 70 per cent alcohol was injected in the vicinity of the appropriate ganglion after the preliminary injection of novocain.

The surgeons used vitamin preparations, but did not have so much confidence in this form of therapy as did the internists. Information was volunteered that children with infections who had been treated

in relatively dark bombproof hospital pregnancy on as six months and had got little sun. I do about as well as did those treated to a high hospitals where plenty of sunshine was a lowering. Vitamin K did not seem to be used extensively at all. Patients with intense jaundice were with calcium and blood transfusions.

There was no evidence of the use of plasma type of amino-acid preparations for the intravenous therapy of malnutrition. ¹⁹²⁸

Although there was general agreement that widespread use of whole-blood transfusion constituted one of the major advances of the war, there was little evidence that the actual requirements of whole blood in the various surgical conditions were understood. Transfusion was largely effected by an antiquated direct method, although occasionally the citrate method was employed, neither glucose nor refrigeration seemed to have been in use as a preservative in civilian hospitals. Each city had a list of donors, usually workers in large nearby factories, so that whole blood was readily available. The donors were paid 25 marks for each transfusion (500 cc.), and in addition were given extra coupons for food rations, these incentives were sufficient to ensure an adequate supply of donors at all times. Wet plasma was available, but neither the dosage of blood nor that of plasma appeared to be controlled by laboratory tests or to be based on previous scientific estimations of the requirements for any particular type of case. No information concerning the use of plasma substitutes was obtained.

The operating rooms in the various clinics did not contain a single modern anesthesia machine. It may be that some of these machines had been sent to the Army or stored outside the city for protection against bombing. It could not be determined, however, that the surgeons employed gas anesthesia, and they seem to have had little experience with intratracheal anesthesia. They used 0.5 to 1.0 per cent novocain for local anesthesia in many operations, and barbiturates were widely employed intravenously. Ether was used for inhalation anesthesia except in cases presenting pulmonary infection, in which chloroform was used. There was little mention of spinal anesthesia, which was certainly not used in surgery of the upper abdomen. Morphine, pantopon, dilaudid and scopolamine were utilized in various combinations.

No new instruments or modern devices were observed in any of the clinics visited. Some of the surgeons, however, were enthusiastic about the use of long metal rods that were introduced into the medullary canal in the treatment of fractures of the long bones, especially those of the femur. They did not employ scalpels with detachable blades. Sewing clamps of the von Petz type were available for gastric and intestinal surgery. In most clinics an electrocoagulation and a cutting unit were available. Casual observation tended to confirm the

Research

It was evident that there was little opportunity for research, and as a result few significant contributions in this field were made during the war. Although the various professors appeared to be of high caliber, and had in the past carried out or supervised extensive research projects, this activity during the war was greatly curtailed by many factors. In the first place, as already mentioned, the number of assistants was decreased by half. The students were of such poor quality that few had either the time or the inclination to assist in research projects. In some instances the professors had served for long periods as consultants in the Army. On their return to civilian life they were burdened with a tremendous professional load of civilian patients and casualties from air raids. In some cases extensive damage had been done to the clinics and laboratories, which further impeded research. In some clinics all the surgery had been performed during the past eighteen months in bomb-proof, partially underground hospitals of limited space. There was also an understandable shortage of drugs and supplies for patients, let alone research projects. The majority of professors, however, attempted to continue their investigations pertaining to subjects that had interested them for years, but many times they were unable to publish their findings or to have reprints of their articles made because of the paper shortage, or because of arbitrary discriminations of one kind or another made by Nazi officials. Apparently the latter were especially active in curtailing the publication of articles pertaining to a medicohistorical subject.

It is fair to say that individually the professors expressed resentment of the occasional appointment by the Nazis of inferior men to head departments, although such interference was apparently limited to certain universities. Furthermore, they appreciated keenly the loss to the universities in the last few years of some men as a result of racial discrimination. Inquiry was made of each professor regarding what he considered to be the greatest advance made during the war, invariably the answer was, "The use of sulfonamides." Second in importance was the rather widespread use of whole-blood transfusion. Penicillin had never been made available.

MEDICAL PRACTICE

Surgery

Specific inquiry was made concerning the principles of therapy utilized for some of the more frequent general surgical conditions. The various specialties were not evaluated. Although the basic principles of good surgery appeared to be thoroughly understood, it was evident that many practices were years behind the times. Although the individual clinics may have standardized their procedures, there was little evidence given by the men

who had served as senior consultants in the Army that a systematic routine for the management of battle casualties was practiced.

Sulfonamide therapy was considered the greatest advance of the war, and many different varieties of the drug, comparable to those available in the United States, were utilized. Although enthusiastically the surgeons did not have so much confidence in the sulfonamides as did the internists. Certainly, in two of the large clinics they were not sure of the value of sulfonamides when applied locally in open wounds. Apparently both in civilian practice and in the Army it was optional with the surgeon whether sulfonamides were dusted into wound. They all emphasized that adequate surgery was more important than chemotherapy. Sulfonamides were used in the treatment of gas gangrene, but the surgeons had no confidence in their effectiveness.

All wounds were débrided if seen within forty-eight hours after the time of injury, and the majority were left open. The value of early secondary closure for most wounds was not appreciated. A few large wounds were secondarily closed from five to seven days after débridement, but this was not a routine procedure in either civilian or Army practice.

Gas-gangrene antitoxin was used in the Army for wounds in susceptible areas, such as those of the upper thigh. There was general agreement that adequate radical surgery was the only efficient method of preventing gas gangrene, as well as of treating it after infection had developed. Little confidence was expressed in gas-gangrene antitoxin or the sulfonamide drugs in the management of such cases.

Relatively little tetanus was seen in civilian practice, although there had been a noted increase during the last six months. There was a tendency to attribute this to the fact that the recently manufactured antitoxin was probably defective. Tetanus antitoxin seems to have been given to all wounded men, and tetanus toxoid was reserved for special troops. Once tetanus had developed, it was treated by the daily injection of antitoxin, either intravenously or intrathecally. Avertin was used to control muscle spasm.

The treatment of burns appeared to be fairly standardized in the several clinics visited. In most of them the wound was débrided by brushing and by the application of alcohol under general anesthesia. Following this, a powder, whose active principle was tannin, was applied and the area was covered with dry gauze. In some cases boric acid and vaseline — and in others cod-liver oil — were applied to the burned areas. There was a tendency to give whole-blood transfusions daily, plasma was given only as a substitute. Pressure dressings, immobilization, early skin grafting and the requirements of blood and plasma replacement were not appreciated.

normal limits. The peaks, too, were normal except in rare cases. The two-hour levels during pregnancy were abnormally high in a large percentage of cases (81 per cent). For this reason, a high two-hour level cannot be considered diagnostic of diabetes during pregnancy. On the other hand, the three-hour level was normal during pregnancy with one exception and may thus be more properly used as a criterion. The incidence of high two-hour values persisted immediately after delivery but dropped sharply after the puerperium. These find-

ings indicate an adverse effect of pregnancy on carbohydrate metabolism.

Pregnancy glycosuria is probably due to a high alimentary hyperglycemia rather than to a lowering of the renal threshold.

MECKEL'S DIVERTICULUM*

With Report of a Case of Intussusception Due to Its Invagination

WARREN G. ATWOOD, M.D.†

FALL RIVER, MASSACHUSETTS

THE presence of an appendage or diverticulum in the small intestine was observed by Lavater¹ as early as 1672. In 1700, Littré described a structure that was probably a true congenital diverticulum, but stated that the appendage lacked the usual muscular coats.² Both Ruysch and Mery recorded the phenomenon in 1701.³ Ruysch was the first to name it "diverticulum," and his *Thesaurus Anatomicus* contains an illustration of this blind sac. Morgagni⁴ in 1769 mentioned several cases of diverticulum of the ileum and suggested their embryologic origin, having previously noticed this type of diverticulum in geese. Sandifort⁵ described a case of acute intestinal obstruction probably due to Meckel's diverticulum as early as 1793. But inasmuch as Meckel⁶ was the first to give an extensive description of this structure, with an explanation of its origin and clinical importance, his name was given to this particular diverticulum of the ileum. He described it as an embryonic rest or remnant of the vitelline duct that had failed to become obliterated.

The earliest known case of an anatomic specimen of this appendage is that placed in the anatomical museum of St. Bartholomew's Hospital, London in 1846.⁷ The ornithologist Elliot Coues mentions finding this abnormality in birds and explains the variability of the site along developmental lines.⁸

In 1933, Harkins⁹ published a report of 160 cases collected from the literature and added 2 of his own. A number of authors⁹⁻¹⁹ have reported cases since this date, but little additional information is to be obtained from these cases beyond Harkins's conclusions. After reviewing the literature, he stated that Meckel's diverticulum occurs in normal people in 13 per cent of cases and is three times as frequent in males as in females. Many authors claim that

75 per cent are found in males. Meckel's diverticulum is found in 2 to 3 per cent of all autopsies. Intestinal obstruction from this abnormality occurs in an extremely small percentage of cases—1.5 per cent according to Harkins, 3 per cent according to Richardson and 6 per cent according to Halsted and Lichtenstern.²

The obstruction may be brought about in any one of a number of ways. The obliterated omphalomesenteric duct in the form of a fibrous band may constrict the bowel. The tip of the diverticulum may attach itself to some point in the peritoneal cavity and act as a constricting band. A long, mobile diverticulum may tie a knot around a loop of free bowel, as in Dorling's²⁰ case, in which the ileum was thus involved. A long diverticulum—the average diverticulum according to Lamb²¹ is 5 cm. long—may become adherent to the intestine or umbilicus and act as a band, causing strangulation or volvulus. The diverticulum may invaginate itself into the lumen of the bowel and start an intussusception, in which case a polyp is often present in the diverticulum. The first case of this sort was cited by Moroni²² in 1898. A starting point may be the expulsion of a fecal mass or concretion from the lumen of the diverticulum into the intestine. The diverticulum becomes inverted and acts as a polyp, initiating an intussusception. The mesentery is usually dragged into the intussusception and the traction causes pain. McCann² states that to invert a Meckel's diverticulum must hang free. As a rule, there are secondary attachments to the intestine, mesentery or umbilicus. Peristalsis of the diverticulum itself may cause inversion with negative pressure exerted by the rapid flow of intestinal contents. Inflammation may cause swelling at the base of the diaphragm and inversion into the lumen of the intestine. The bowel attempts to expel it, and this causes bleeding and inversion of the mucosa and serosa.

Sometime during pregnancy	81
Immediately after delivery	47
Postpartum	15

of abnormal two-hour levels occurred in the second and third trimesters and after delivery. Occasional values were as high as 164 mg per 100 cc. Only 2 patients in the post-partum group had high levels, and these were just over the critical level — 121 and 127 mg, respectively.

All the three-hour levels were normal throughout pregnancy and the post-partum period, except for two high values in 1 case. The values in this case are given in Table 2. There was an extremely

TABLE 2 Results of Glucose-Tolerance Tests in a Single Case

PERIOD	FASTING LEVEL mg / 100 cc	PEAK LEVEL mg / 100 cc	2 HOUR LEVEL mg / 100 cc	3 HOUR LEVEL mg / 100 cc

Third trimester	93	162	131	122
Immediately after delivery	88	161	147	110
Postpartum	90	160	97	105

*Patient first seen in second trimester

high three-hour level — 155 mg — in the first test. This followed a lower two-hour level, which suggests a technical error. The next curve gave a three-hour level of 122 mg, which is just over the normal value. Subsequent curves were normal.

DISCUSSION

The above data indicate that normal pregnancy exerts a deleterious effect on carbohydrate metabolism, as is shown by the distortion of the glucose-tolerance tests. Two-hour blood-sugar levels over 120 mg were extremely frequent, especially during and after the second trimester. These persisted after delivery but returned to normal several months post partum. It is during the second trimester that diabetes often appears and that pre-existing diabetes is made worse.³ Obviously, if a high two-hour blood-sugar level is considered diagnostic of diabetes, many normal pregnant patients — 81 per

cent of this series — would be so diagnosed. On the other hand, all the three-hour levels during pregnancy were normal except for those in 1 patient in whom subsequent determinations during pregnancy were normal. It is apparent that diabetes should not be diagnosed during pregnancy except when the most stringent criteria are applied — a high fasting blood sugar (over 120 mg per 100 cc but preferably over 130 mg) or a high three-hour level (over 120 mg). Even then an occasional case may show a return to normal after the puerperium.

In regard to the question of glycosuria during pregnancy, it is of interest that of the 4 patients who showed large amounts of sugar in the urine during the glucose-tolerance test, all but 1 had high blood sugars — over 180 mg — at the time of the glycosuria. Figure 2 illustrates this fact. Glycosuria

FIGURE 2 Glucose-Tolerance Curves on the Same Patient at Various Times during Pregnancy and after Delivery. Note the association of marked glycosuria with hyperglycemia.

during pregnancy is usually ascribed to lowering of the renal threshold. From this figure it is readily apparent that significant glycosuria occurred at the time of or soon after a marked elevation in the blood sugar. Since the curve dropped to normal, it is justifiable to classify these curves as those of high alimentary hyperglycemia.

SUMMARY AND CONCLUSIONS

Serial glucose-tolerance tests were done on 25 normal pregnant patients — at each trimester, immediately after delivery and several months post partum.

The fasting blood-sugar values were well within

diverticulum On reduction of the intussusception, a dimple was found in the ileum at the point where the diverticulum inverted into the lumen of the bowel (Fig 1c) It was believed that a piece of green apple was the exciting cause of the intussusception No polyp was present

With considerable difficulty, the bowel was replaced in the abdominal cavity During this procedure the patient's condition caused anxiety Fluid was withdrawn from the stomach through a Levin tube The pulse was of poor quality and the skin color fair The patient's condition improved with the administration of oxygen and intravenous glucose No further operative measures were attempted The abdomen was closed with several mass interrupted nylon sutures through the peritoneum, muscle, fascia and skin

At the close of the operation, which lasted for 25 minutes the patient's condition was critical In spite of oxygen and supportive treatment, it became steadily worse, and death occurred 1 hour after operation Permission for an autopsy could not be obtained

In these cases a definite history of previous abdominal crises is fairly frequent In many there is a less severe attack a day or two before the final attack that sends the patient to the hospital One explanation is that the diverticulum becomes inverted before the bowel becomes invaginated

Colicky pain is present in almost every case reported Vomiting is present in 92 per cent of cases, and is a cardinal symptom out of proportion to other symptoms Tenderness and rigidity may not be present, even when the bowel is gangrenous A mass is almost always present, usually in the right lower quadrant of the abdomen The mass is rarely found palpable by rectum There is little fever or elevation of the white-cell count Melena may or may not be present The condition is usually taken for acute appendicitis or for intussusception from other causes Indications for operation are the same in both conditions, so that the differential diagnosis is of but academic interest

Harkins⁷ states that the mortality in children is 56 per cent — 36 per cent in those over five years of age and 74 per cent in those under one year of age In many cases the diagnosis is made too late and operation is done only as a last resort when the pa-

dition and the diverticulum is not gangrenous, it should not be excised The intussusception may be treated by simple disinvagination Often, however, a one-stage or two-stage resection is necessary Bowel resection is less dangerous than it is in cases of ordinary intussusception, because most of the patients are older In Harkins's⁷ series the average age was twenty-one years Bickham²³ advises excision

TABLE 2 Type of Operative Treatment

OPERATION	No of Cases
Excision of Meckel's diverticulum only*	4
Excision of Meckel's diverticulum and resection of portion of ileum	15
Excision of Meckel's diverticulum and appendectomy	1
Appendectomy only	1
Cholecystectomy only	1
Repair of inguinal hernia	1
Reduction of intussusception only	1
	24

*In 1 case appendectomy had been done previously

of the diverticulum by a transverse elliptical incision, which should not be deep enough to result in encroachment on the lumen of the bowel The appendix should not be removed unless it is gangrenous or has thrombosed vessels When resection of the Meckel's diverticulum is considered feasible, a stricture may result from inversion with a purse-string suture After the diverticulum has been excised by a wedge-shaped incision, the intestine should be closed transversely to the long axis of the bowel Harris¹⁰ makes an appeal to the surgeon to direct his mind from appendicitis in cases that are not clear cut In cases of this sort, if a simple appendectomy is performed, the patient is frequently again taken ill with an attack like the first one Furthermore, pain caused by a diverticulum is often considered to be due to adhesions, enteritis or colitis or the pelvic organs are blamed

SUMMARY

The literature on the subject of intussusception due to an invaginated Meckel's diverticulum has been reviewed, and an additional case is reported On admission the cause of the obstruction presented a problem in diagnosis, which was revealed at laparotomy

The mechanism of the inversion of the Meckel's diverticulum to produce intussusception is illustrated

This case, which ended fatally, illustrates the need of early diagnosis and surgery, while the patient is still a good operative risk and also the need in any laparotomy of a search for a Meckel's diverticulum, especially in children

tient is in extremely poor condition The benefit of early operation is seen in the statistics from his analysis of 160 cases (Table 1)

The treatment in the 24 operative cases at the Truesdale Hospital is shown in Table 2 In the case in which only appendectomy was done, the Meckel's diverticulum was noted, but it had a large base and was not excised The case in which cholecystectomy was done was complicated by a three-month pregnancy

Sniglev,¹¹ who reports a series of 4 cases with recovery, states that if the patient is in poor con-

Meckel's diverticulum is usually found 30 to 45 cm proximal to the ileocecal valve, but it may occur at any point between the pylorus and the ileocecal valve — as a rule in the lower fourth of the ileum. Ordinarily it arises from the bowel opposite the attachment of the mesentery, but it may arise at either side or between the two leaves. In infants, it is often found nearer the ileocecal valve, because the site

Physical examination on admission showed a well developed, fairly well nourished, slender boy, complaining of severe abdominal pain. The lips were cyanotic, and the general condition was extremely poor. The temperature was 100.6°F, the pulse 130, and the respirations 22. The respirations were labored and slightly increased. There was a marked odor of acetone on the breath. The lungs were clear and resonant, and no rales were heard. The heart sounds were of fairly good quality, with a rapid rate. The abdomen was markedly distended and tympanitic to percussion, with generalized tenderness. No peristalsis was heard. The pa-

FIGURE 1

depends on the amount of growth in the portion of the intestine proximal to the insertion of the omphalovitteline duct.

Thirty-seven cases of Meckel's diverticulum have been recorded at the Truesdale Hospital in 69,000 admissions. Thirteen of these were found at autopsy. Intussusception as a result of inversion of the diverticulum occurred in only 1 case, which is reported below.

CASE REPORT

A S. (65619), a 7-year-old boy, was admitted to the Truesdale Hospital on July 10, 1944. The mother stated that symptoms began on the morning of July 8, when the patient complained of severe abdominal pain, accompanied by nausea and vomiting. He had been eating green apples, and the mother thought that he had an ordinary stomachache. The pain continued during the following day, along with the nausea and vomiting. Early on the morning of July 10, the family physician was called. By that time the patient was lethargic and cyanotic. There was an odor of acidosis on the breath, and the abdomen was distended. He immediately referred the patient to the hospital. There was no history of any previous similar attack.

The patient was thought to have acute intestinal obstruction from an unknown cause.

Urinalysis showed the slightest possible trace of albumin, large numbers of hyaline casts, a rare pus cell and mucus. The hemoglobin was 80 per cent, the red-cell count 4,440,000, and the white-cell count 14,650, with 69 per cent neutrophils, 20 per cent lymphocytes, 2 per cent large mononuclear leukocytes, 8 per cent band forms, and 1 per cent metamyelocytes.

The patient was extremely restless from the time of admission. The pulse was rapid and weak. He vomited at frequent intervals. A rectal tube was inserted, and 1000 cc. of 5 per cent glucose in saline solution was given by clysis.

At 2:20 p.m. the patient was taken to the operating room, where exploratory laparotomy was done under nitrous oxide, oxygen and ether anesthesia. The abdomen was opened through a right-rectus muscle-splitting incision. A considerable amount of foul-smelling fluid was present in the abdominal cavity. The small intestine was markedly distended and ballooned out of the abdomen. At that point, the patient vomited large quantities of foul-smelling fluid, suction was used, with a reasonably good result. His condition, however, was only fair.

By following along the small intestine in the direction of the cecum, a point of obstruction was located in the terminal ileum that had prolapsed through the ileocecal valve (Fig. 1a). The mechanism of the inversion and intussusception is shown in Figure 1b. The intussusception was reduced by expulsion and milking. At its apex was an inverted Meckel's

diverticulum On reduction of the intussusception, a dimple was found in the ileum at the point where the diverticulum inverted into the lumen of the bowel (Fig 1c) It was believed that a piece of green apple was the exciting cause of the intussusception No polyp was present

With considerable difficulty, the bowel was replaced in the abdominal cavity During this procedure the patient's condition caused anxiety Fluid was withdrawn from the stomach through a Levin tube The pulse was of poor quality and the skin color fair The patient's condition improved with the administration of oxygen and intravenous glucose. No further operative measures were attempted The abdomen was closed with several mass interrupted nylon sutures through the peritoneum, muscle, fascia and skin

At the close of the operation, which lasted for 25 minutes the patient's condition was critical In spite of oxygen and supportive treatment it became steadily worse, and death occurred 1 hour after operation Permission for an autopsy could not be obtained

MEDICAL PROGRESS

SYPHILIS

G MARSHALL CRAWFORD, M D *

BOSTON

THE use of penicillin in syphilotherapy has become so widespread and the volume of literature regarding this drug so voluminous that this year's progress report on syphilis is being presented in slightly different fashion. A separate main division is devoted to penicillin and placed at the end of the report.

PUBLIC HEALTH

Little literature has appeared during the past year regarding the public-health aspects of syphilis. This may be due to some degree of optimism resulting from the remarkable reduction in the incidence of venereal disease during World War II. Never in history has any nation been able to accomplish such a feat. Despite this fact, control of venereal disease in the civilian population continues to be a tremendous problem. Editorial comment¹ cautions against overoptimism regarding its eradication. The recent advances in therapy, although highly effective, will not eliminate venereal disease unless more vigorous epidemiologic control is maintained. The establishment of rapid-treatment centers in many parts of the country, with the assistance of the United States Public Health Service through funds made available by Congress, is an example of what should now be done on a broader scale. By present methods of administration, penicillin treatment requires a week or more of hospitalization, and sufficient beds are not available. Syphilis must be dealt with in the same fashion as any other highly communicable disease, with the

co-operation of federal, state and local public health services, before the disease can be wiped out.

Incidence of Syphilis

Statistics are available on the incidence of syphilis in the first six months of the fiscal year 1944-1945, from the Health Officers' Monthly Statements.² The total amount of syphilis (171,535 cases) reported in the United States was approximately 25 per cent less than that reported during the first half of the preceding fiscal year. During the same period of time, primary and secondary syphilis (36,445 cases) continued to appear at nearly the same rate of incidence as in the year before. The latter figure indicates that public-health control measures have been holding the incidence of new infections about stationary. The decrease in total syphilis reported suggests that the reservoir of old infections is gradually being brought under treatment. If this is true, there should be a decrease in the amount of late crippling disease encountered hereafter.

The results of the first statutory requirement for mass civilian blood testing are now available. In July, 1943, the Legislature of Alabama passed a law requiring all civilians between the ages of fourteen and fifty to have their blood examined for syphilis. In the first three counties surveyed,³ it was found that 80 to 90 per cent of the population voluntarily appeared to be tested, indicating that law-enforcement agencies will have to play but little part in the program. The Whites showed 2.2 per cent positive tests, and the Negroes 20.5 per cent. This is the commencement of an ideal campaign to eradicate syphilis. It will be time-consuming and expensive, but if continued on a nation-wide basis

*Instructor in dermatology Harvard Medical School assistant dermatologist, Massachusetts General Hospital

may well constitute one of the greatest single public-health measures in history

Control Measures

A summary of the contribution of the military forces toward postwar control of venereal disease⁴ indicates a number of advantages that should greatly benefit the civilian population. A tremendous number of physicians and lay personnel trained by and educated in the military services regarding the principles of venereal-disease control will return to civilian life and will be available as workers in connection with venereal-disease control programs. Several million men who have received intensive venereal-disease education will return and should raise the level of information among the general public. Mass wartime experiences with the remarkable advances in treatment have contributed greatly to the therapeutic armamentarium. These factors present an unusual opportunity to reduce the incidence of venereal infection to a more readily controllable minimum.

The growth of programs for the control of venereal disease in industry is an encouraging circumstance. Anderson⁵ has surveyed the accomplishments in this field, pointing out the co-operative achievements by both labor and management, and outlines the basic principles set down for the management of syphilis in industry by the United States Public Health Service. Industrial physicians, by following the medical objectives of an industrial venereal-disease control program and co-operating with state and local health departments, can be of great service in establishing intelligent control measures.

An analysis of case-finding measures⁶ in venereal-disease control indicates that in the area surveyed more persons with infectious lesions voluntarily applied for aid than were brought under care by any other means. This illustrates the value of community education and of publicizing the availability of services. Although mass blood testing on a large enough scale will uncover more syphilis than will any other method of case finding, it will be severely handicapped unless intensive community education is successfully carried out.

An interesting report⁷ on the value of educational procedures among the general public has appeared. A county in Georgia with a population of approximately 40,000, half being Negroes, was selected. Adequate facilities for diagnosis and treatment were provided. The community was then made aware of the prevalence of venereal disease, the facilities available and the newer methods of therapy. Every measure was taken to encourage patients to seek examination, either by private physicians or at public clinics. It was found that of the patients who came voluntarily to public-treatment centers, 76 per cent were directed to the clinic by posters seen in public lavatories. Negro churches were

utilized to disseminate information on venereal disease. An effort was made to encourage teaching on venereal disease in the schools for Negroes. Both these measures also proved of value, especially from the standpoint of improvement in knowledge of venereal disease. This report is an example of what can be accomplished even among the least privileged citizens.

Cost of Syphilis

Estimating with any accuracy the financial burden imposed yearly on the Nation by this single disease is probably a near impossibility. A study is available, however, on the economic cost of paresis.⁸ The data were obtained from a survey of admissions to state, county, city, private and Veterans Administration hospitals. The annual direct cost to the taxpayer of maintaining paretics is over \$11,000,000. The loss of income to the paretic patients themselves is estimated at \$112,000,000 yearly for men alone. These figures are astounding, especially when one considers that paresis is only one of the late manifestations of syphilis and not the only cause of insanity due to the disease.

EXPERIMENTAL STUDIES

Aside from the vast amount of research related to penicillin in the treatment of syphilis, the main field of study has been related to hepatic dysfunction during the chemotherapy of syphilis. One investigator in particular, Dr A. C. Ivy, has for many years made an intensive study of the physiology and diseases of the liver. The excretion of neoarsphenamine arsenic and Mapharsen arsenic in the bile of dogs with permanent bile fistulas has recently been investigated by Ivy and his co-workers.⁹ It was found that 40 per cent of the arsenic in Mapharsen was recovered in the bile in forty-eight hours, whereas the same percentage from neoarsphenamine was recovered in seventy-two hours. The production of choleresis in dogs did not augment the rate of excretion of arsenic in bile, and arsenic excreted in the bile was not thoroughly absorbed from the intestine. The administration of sodium dehydrocholate tended to decrease the elimination of arsenic, and the administration of sodium glycocholate and taurocholate, which cause less choleresis, increased the elimination of arsenic in the bile. If the administration of dehydrocholic acid diminishes the hepatotoxic action of neoarsphenamine and Mapharsen, it apparently does not do so by increasing their excretion in the bile. It was thus concluded that these results obviously do not provide a clear and substantial rationale for the administration of bile acids with arsenicals. Further work by the same group of investigators¹⁰ indicated that neoarsphenamine does not constantly depress the output of cholic acid in dogs with a permanent biliary fistula. Mapharsen did constantly depress this output in

MEDICAL PROGRESS

SYPHILIS

G MARSHALL CRAWFORD, M D*

BOSTON

THE use of penicillin in syphilotherapy has become so widespread and the volume of literature regarding this drug so voluminous that this year's progress report on syphilis is being presented in slightly different fashion. A separate main division is devoted to penicillin and placed at the end of the report.

PUBLIC HEALTH

Little literature has appeared during the past year regarding the public-health aspects of syphilis. This may be due to some degree of optimism resulting from the remarkable reduction in the incidence of venereal disease during World War II. Never in history has any nation been able to accomplish such a feat. Despite this fact, control of venereal disease in the civilian population continues to be a tremendous problem. Editorial comment¹ cautions against overoptimism regarding its eradication. The recent advances in therapy, although highly effective, will not eliminate venereal disease unless more vigorous epidemiologic control is maintained. The establishment of rapid-treatment centers in many parts of the country, with the assistance of the United States Public Health Service through funds made available by Congress, is an example of what should now be done on a broader scale. By present methods of administration, penicillin treatment requires a week or more of hospitalization, and sufficient beds are not available. Syphilis must be dealt with in the same fashion as any other highly communicable disease, with the

co-operation of federal, state and local public health services, before the disease can be wiped out.

Incidence of Syphilis

Statistics are available on the incidence of syphilis in the first six months of the fiscal year 1944-1945, from the Health Officers' Monthly Statements.² The total amount of syphilis (171,535 cases) reported in the United States was approximately 25 per cent less than that reported during the first half of the preceding fiscal year. During the same period of time, primary and secondary syphilis (36,445 cases) continued to appear at nearly the same rate of incidence as in the year before. The latter figure indicates that public-health control measures have been holding the incidence of new infections about stationary. The decrease in total syphilis reported suggests that the reservoir of old infections is gradually being brought under treatment. If this is true, there should be a decrease in the amount of late crippling disease encountered hereafter.

The results of the first statutory requirement for mass civilian blood testing are now available. In July, 1943, the Legislature of Alabama passed a law requiring all civilians between the ages of fourteen and fifty to have their blood examined for syphilis. In the first three counties surveyed,³ it was found that 80 to 90 per cent of the population voluntarily appeared to be tested, indicating that law-enforcement agencies will have to play but little part in the program. The Whites showed 2.2 per cent positive tests, and the Negroes 20.5 per cent. This is the commencement of an ideal campaign to eradicate syphilis. It will be time-consuming and expensive, but if continued on a nation-wide basis

*Instructor in dermatology. Harvard Medical School assistant dermatologist, Massachusetts General Hospital.

such reactions have been reported. Such diseases have been listed in these columns several times in recent years and will not be repeated at this time. It seems altogether possible that some of the diseases that Davis includes may not have been responsible for the false-positive reactions, since their incidences are so extremely low. Serologic tests for syphilis are subject to marked variations in sensitivity, which may account for a large proportion of discrepancies in published reports of false-positive reactions in various diseases. Technical errors also must not be forgotten. Davis stresses the importance of a sufficient period of observation, except during pregnancy, before making a final diagnosis in questionable cases. He indicates a period of three months, but a much longer time is often necessary. A point that is stressed is that a positive serologic test for syphilis is not an emergency. This is obviously true in the absence of infectious lesions, but neither should positive tests be lightly regarded, as so often occurs. Even the best trained men in other fields of work, from time to time, pay too little attention to positive serologic tests for syphilis and do not seek expert advice until the development of clinical lesions. These may be of minor clinical import, but they are not infrequently most distressing to the patient and are completely unnecessary.

Numerous reports on the effect of malaria on serologic tests for syphilis continue to appear. In a series of more than eight thousand tests carried out by six standard techniques, the Hinton flocculation test for syphilis showed the smallest proportion of false-positive reactions in malaria of any of the serologic techniques employed.²² It was stated that in the absence of continued evidence of malarial infection, the persistence of positive reactions to any serologic test beyond a period of six weeks should arouse the suspicion of syphilis. This is a shorter time period than some observers have reported in the past, but agreement with a six-week time factor is available.^{23, 24} Spinal-fluid examinations made on 100 malaria patients within forty-eight hours after hospitalization were found to be essentially normal.²⁴ Slight deviations from normal occurred in the spinal-fluid findings of 4 cases, but these were not indicative of syphilis and there were no neurologic symptoms.

Favorite²⁵ has continued his study of false-positive reactions for syphilis due to smallpox vaccination (vaccinia). Five hundred and twenty-five cases are included in his latest report. Of 202 patients on whom a single blood examination was performed, 11.8 per cent gave positive reactions. These appeared within two weeks of the date of vaccination and usually disappeared within two months, but a few weakly positive reactions persisted for as long as four months. A second group of 323 persons, who had had smallpox vaccinations several months previously, were given typhoid vaccine and tetanus toxoid to determine the role played by immuniza-

tion. No significant bearing on the production of false-positive serologic reactions for syphilis was observed. Recently vaccinated persons who had exhibited a temporary false-positive reaction did not have a reactivation of the reaction following typhoid and tetanus immunizations. It was found, however, that if these patients were revaccinated for smallpox within seven months, they might again present a weak serologic false-positive response for syphilis, even though the second vaccinia reaction was of the immune type. In a series of 129 patients with vaccinia reported during the past year, 44.9 per cent showed falsely doubtful or positive tests with one or more serodiagnostic procedures.²⁶ This is an extremely high incidence compared with that in most reports in the literature. The application of the Kahn verification test to post-vaccination false-positive serologic reports has apparently been useful.²⁷

In contrast to Favorite's²⁵ experience with tetanus toxoid, other observers²⁸ report 8 cases in which biologic false-positive serologic reactions were considered to be directly related to stimulating doses of tetanus toxoid. Infectious hepatitis was apparently responsible for fifteen false-positive or doubtful serologic reactions after the clinical appearance of jaundice in 63 patients among allied military personnel in Sicily.²⁹ All but one of the reactions were negative by the seventh week. During an epidemic of upper respiratory infections among troops in this country, 100 patients were found to have positive serologic reactions for syphilis.³⁰ All had received routine Army immunizations from five days to four months previously. In 90 per cent of these cases, the false-positive nature of the serologic reactions was established. That the upper respiratory infection played any appreciable role in these false-positive cases seems doubtful.

CLINICAL PROBLEMS

The third edition of *Modern Clinical Syphilology*, by Stokes,³¹ appeared some months ago. This superb book on the diagnosis and treatment of syphilis has been brought up to date by the rewriting of a large proportion of the text and the addition of chapters on penicillin, military medicine and public health. Stokes's favorite and effective "thumbnail summaries" are featured as before. This magnificent work should be in the possession of everyone who is interested in syphilis.

Reinfection

On numerous occasions in the past, the criteria for the cure of syphilis and for the diagnosis of reinfection with the disease have been discussed in these columns. The advent of intensive treatment programs and more lately the startling effectiveness of penicillin have necessarily brought about changes in the concept of such reinfection. It becomes increasingly difficult to differentiate relapse and re-

such dogs when the animals were deprived of bile acids. The oral administration of dehydrocholic acid may assist in counteracting the hepatotoxic action of Mapharsen. These findings led to the suggestion that patients scheduled to receive intensive arsenotherapy should for two or three days prior to the initiation of therapy have a liver-function test and be given a diet known to affect favorably the liver's resistance to poisons. Adequate protein is the essential feature of this diet.¹¹ Other workers,¹² studying liver damage from Mapharsen in dogs, present evidence that the oral administration of methionine affords protection against hepatic injury following large doses of Mapharsen given to protein-depleted dogs. Clinical application of this work indicates that the oral administration of methionine and cystine are effective in delaying the onset of liver damage and in diminishing the severity of the hepatitis in human beings treated with neoarsphenamine, but has no effect on the total incidence of liver damage.¹³

It is obvious from the reports of these several groups of investigators that the hepatotoxic effect of organic arsenical compounds is not too well understood. Present indications are that less and less arsenic will be used hereafter, if penicillin proves to be all that is hoped. It seems unlikely, however, that a form of chemotherapy that has stood so well the test of time can be completely discarded, and it is to be hoped that further study of these drugs will be continued.

SEROLOGIC PROBLEMS

Considerable attention has been devoted during the past year to the blood serologic aspects of syphilis. There is a continuous striving to improve technic in the performance of blood tests and to eliminate the false-positive findings that are not infrequently encountered. But few of the reports in this field will be quoted, since much of the literature is of no direct value to the practicing physician. An excellent general discussion of the serologic findings in early syphilis is available.¹⁴ It is pointed out therein that a limited serologic routine furnishes sufficient data for the usual diagnostic purposes and for the evaluation of clinical response to an established treatment. This justifies the performance of only one or two reliable tests, as carried out by most hospitals, state health departments and city laboratories.

The more highly refined quantitative tests are mainly valuable in gauging serologic response, such as a decreasing titer or the development of a serologic relapse. Their usefulness is thus limited to certain special situations and research projects. An extensive battery of different tests falls in the same category. Kahn¹⁵ has published a short bulletin intended to serve as a practical guide to the technics of the various serologic tests that he has devised for the examination of serum and of spinal fluid.

The bulletin also outlines the method of interpreting and reporting these tests. This is a useful manual, especially for those engaged in laboratory work.

The indications for quantitative serologic tests for syphilis were reviewed in this journal some months ago.¹⁶ Briefly enumerated, these include the diagnosis of primary syphilis in dark-field-negative lesions, comparative reagin titers in mother and child when congenital syphilis is suspected and the detection of impending relapse, including the clarification of certain technical points. Quantitative procedures estimate the potency (amount of reagin), in the same general fashion as in the Widal reaction, by quantitative titration of the serums. Some authors¹⁷ advocate general adoption of these procedures for use in the management of every phase of syphilis. Limitations of their usefulness, possible difficulties of interpretation in general practice and the expense involved seem to preclude their widespread application at the present time.

Still further refinements in serologic technics are the verification tests that have been devised to assist in identifying false-positive serologic reactions. After extensive experience, Rein and Callender¹⁸ believe that the average serologist is not able to distinguish consistently between true-positive and false-positive reactions by the use of any verifying test yet devised. They consider these tests, for the present, in the experimental stage and stress the oft-repeated caution that a diagnosis of syphilis should not depend on serologic reactions alone. The ensemble of available data, before diagnosis, should include the history and physical examination, radiologic studies, spinal-fluid findings and examination of contacts and family, in addition to repeated serologic reports from more than one laboratory. Additional measures may be necessary to rule out nonsyphilitic diseases that may cause false-positive serologic reactions. A discussion of the principles of verification tests is available,¹⁹ with a description of the chemical and immunologic aspects of the reactions of syphilitic and false-positive serums. The possibility of the application of verification tests to the development of a practical method of differentiation is encouraging.

False-Positive Reactions

General considerations on the occurrence of false-positive reactions for syphilis have been reviewed by Rein and Elsberg.²⁰ Most of this report is concerned with the so-called "biologic" false-positive reactions, occurring in such disease as vaccinia, upper respiratory infections, filariasis, Weil's disease, malaria, typhus fever and leprosy. The incidences of false-positive reactions in these diseases varied from 11.3 per cent in filariasis to 85.0 per cent in leprosy. Davis²¹ reports a review of the literature regarding false-positive reactions for the years 1930-1943. He outlines the long list of diseases in which

such reactions have been reported. Such diseases have been listed in these columns several times in recent years and will not be repeated at this time. It seems altogether possible that some of the diseases that Davis includes may not have been responsible for the false-positive reactions, since their incidences are so extremely low. Serologic tests for syphilis are subject to marked variations in sensitivity, which may account for a large proportion of discrepancies in published reports of false-positive reactions in various diseases. Technical errors also must not be forgotten. Davis stresses the importance of a sufficient period of observation, except during pregnancy, before making a final diagnosis in questionable cases. He indicates a period of three months, but a much longer time is often necessary. A point that is stressed is that a positive serologic test for syphilis is not an emergency. This is obviously true in the absence of infectious lesions, but neither should positive tests be lightly regarded, as so often occurs. Even the best trained men in other fields of work, from time to time, pay too little attention to positive serologic tests for syphilis and do not seek expert advice until the development of clinical lesions. These may be of minor clinical import, but they are not infrequently most distressing to the patient and are completely unnecessary.

Numerous reports on the effect of malaria on serologic tests for syphilis continue to appear. In a series of more than eight thousand tests carried out by six standard technics, the Hinton flocculation test for syphilis showed the smallest proportion of false-positive reactions in malaria of any of the serologic technics employed.²² It was stated that in the absence of continued evidence of malarial infection, the persistence of positive reactions to any serologic test beyond a period of six weeks should arouse the suspicion of syphilis. This is a shorter time period than some observers have reported in the past, but agreement with a six-week time factor is available.^{23, 24} Spinal-fluid examinations made on 100 malaria patients within forty-eight hours after hospitalization were found to be essentially normal.²⁴ Slight deviations from normal occurred in the spinal-fluid findings of 4 cases, but these were not indicative of syphilis and there were no neurologic symptoms.

Favorite²⁵ has continued his study of false-positive reactions for syphilis due to smallpox vaccination (vaccinia). Five hundred and twenty-five cases are included in his latest report. Of 202 patients on whom a single blood examination was performed, 11.8 per cent gave positive reactions. These appeared within two weeks of the date of vaccination and usually disappeared within two months, but a few weakly positive reactions persisted for as long as four months. A second group of 323 persons, who had had smallpox vaccinations several months previously, were given typhoid vaccine and tetanus toxoid to determine the role played by immuniza-

tion. No significant bearing on the production of false-positive serologic reactions for syphilis was observed. Recently vaccinated persons who had exhibited a temporary false-positive reaction did not have a reactivation of the reaction following typhoid and tetanus immunizations. It was found, however, that if these patients were revaccinated for smallpox within seven months, they might again present a weak serologic false-positive response for syphilis, even though the second vaccinia reaction was of the immune type. In a series of 129 patients with vaccinia reported during the past year, 44.9 per cent showed falsely doubtful or positive tests with one or more serodiagnostic procedures.²⁶ This is an extremely high incidence compared with that in most reports in the literature. The application of the Kahn verification test to post-vaccination false-positive serologic reports has apparently been useful.²⁷

In contrast to Favorite's²⁵ experience with tetanus toxoid, other observers²⁸ report 8 cases in which biologic false-positive serologic reactions were considered to be directly related to stimulating doses of tetanus toxoid. Infectious hepatitis was apparently responsible for fifteen false-positive or doubtful serologic reactions after the clinical appearance of jaundice in 63 patients among allied military personnel in Sicily.²⁹ All but one of the reactions were negative by the seventh week. During an epidemic of upper respiratory infections among troops in this country, 100 patients were found to have positive serologic reactions for syphilis.³⁰ All had received routine Army immunizations from five days to four months previously. In 90 per cent of these cases, the false-positive nature of the serologic reactions was established. That the upper respiratory infection played any appreciable role in these false-positive cases seems doubtful.

CLINICAL PROBLEMS

The third edition of *Modern Clinical Syphilology*, by Stokes,³¹ appeared some months ago. This superb book on the diagnosis and treatment of syphilis has been brought up to date by the rewriting of a large proportion of the text and the addition of chapters on penicillin, military medicine and public health. Stokes's favorite and effective "thumbnail summaries" are featured as before. This magnificent work should be in the possession of everyone who is interested in syphilis.

Reinfection

On numerous occasions in the past, the criteria for the cure of syphilis and for the diagnosis of reinfection with the disease have been discussed in these columns. The advent of intensive treatment programs and more lately the startling effectiveness of penicillin have necessarily brought about changes in the concept of such reinfection. It becomes increasingly difficult to differentiate relapse and re-

infection The possibility of superinfection although less likely, should always be kept in mind Cases of supposed reinfection are five to ten times as frequent as in previous years³² The difficulty of adequately differentiating reinfection and relapse is illustrated by the variety of criteria that can be found postulated in the literature The simplest criteria merely require proof of syphilis prior to the occurrence of the supposed second infection This proof must consist of demonstration of spirochetes in the lesion or the occurrence of a positive blood serologic test and should not depend on clinical judgment alone After an interval following anti-syphilitic treatment, and at a site other than that of the primary lesion of the first infection, there must develop a new lesion with the characteristics of a chancre and in which spirochetes can be demonstrated From these simplest criteria, one can go to the opposite extreme of the seventeen complex criteria that are proposed by Stokes In some diseases, reinfection can be considered a proof of cure of a preceding infection Moore³² points out that this is not tenable with syphilis in human beings After discussing the criteria of reinfection at some length, he states this opinion that, at the present time, re-infection cannot be differentiated from relapse on any grounds on which two or more observers would agree He believes that this differentiation must rest on clinical impressions This does not constitute proof Moore points out that until order is brought out of the present confusion, all supposed reinfections must be regarded as treatment failures This is especially applicable to the evaluation of new drugs and new treatment programs

Syphilis of the Mouth

The various forms of syphilis of the mouth are discussed in some detail by Wilson, Dunning and Fox³³ It is pointed out that the dentist has a large responsibility in discovering oral manifestations of systemic diseases The oral lesions of primary, secondary and late syphilis, both acquired and congenital, are described, including those of the lips, tongue, oral cavity, teeth and palate A differentiation from the usual nonsyphilitic diseases that may simulate syphilis of the mouth is given Included in this list are aphthous stomatitis, herpes simplex, herpes zoster, pemphigus, erythema multiforme, lichen planus, lupus erythematosus, leukoplakia, lupus vulgaris, Vincent's infection, granuloma pyogenicum, epithelioma, lingua plicata, lingua geographica, dysvitaminosis, hypovitaminosis, avitaminosis, pellagra, fungous infections and perlèche A word of caution has been written against overlooking the possibility of cancer of the tongue in patients with syphilis³⁴ It is pointed out that cancer can exist in conjunction with syphilis of the tongue in any stage, but may be overshadowed by syphilis when the cancer is early More frequent

biopsies of possibly suspicious areas would provide an earlier diagnosis of cancer and a greater percentage of cures Needless to say, adequate treatment for coexisting syphilis must be diligently pursued

Visceral Syphilis

O'Leary and Ockuly³⁵ point out that the only satisfactory method for determining that a lung lesion is syphilitic is a therapeutic test The symptoms, physical signs and radiologic appearance of pulmonary syphilis are nondistinctive When, however, a patient with positive serologic reactions is dyspneic, coughs, raises bloody sputum, has chest pain, is weak and loses weight and when physical and radiologic examinations indicate a nodular or infiltrative pulmonary process, one may presume that the lung lesion is syphilitic If these signs and symptoms disappear after a course of therapy and do not recur, the opinion that the condition was syphilitic is tenable In a series of 60 patients at the Mayo Clinic in which syphilis of the lung was considered a possibility, this diagnosis was substantiated in only 4 cases Syphilis of the lung rarely recurs following involution under treatment

Among 1705 consecutive adults admitted to a tuberculosis sanatorium for Negroes, 29.7 per cent were found to have positive serologic reactions for syphilis³⁶ These patients were studied from a number of viewpoints without significant findings regarding a biologic relation between the two diseases It has long been believed that the prognosis in such circumstances depends entirely on the tuberculosis, an opinion that was substantiated by this investigation

Syphilis in diabetes has been studied by Perkin³⁷ over a five-year period Among 550 diabetic patients comprising the series, 54 possible cases of syphilis (9.8 per cent) were found The diabetes in the syphilitic group tended to be unusually mild It is the author's opinion that syphilis, as well as all other so-called "causes" of diabetes, is merely a precipitating factor in the potential diabetic patient These cases were observed for varying periods up to twelve years for changes in diabetic status It is stated that there is some relation between latent syphilis in the diabetic patient and the occurrence of gangrene, but the supporting evidence is not too conclusive

Neurosyphilis

An interesting study concerns the incidence of asymptomatic neurosyphilis in young men³⁸ The data were obtained from the spinal-fluid findings of 3000 syphilitic military selectees passing through an induction station Sufficient pathologic changes to cause rejection were found in 294 (9.5 per cent), all but 15 of whom had positive Wassermann reactions in the spinal fluid The second most frequent abnormality was an increased globulin (174 cases) The colloidal gold curve was elevated in 92 cases,

but only 38 of the 3000 spinal fluids showed an increase in cell count

A strikingly low percentage of lumbar-puncture headaches were observed in an army camp³⁹ During a five-month period, lumbar punctures were performed on 2217 syphilitic patients, among whom only 15 (less than 1 per cent) developed post-puncture headache severe enough to require bed rest The fluids were collected rapidly, the patients immediately got on their feet and were instructed to keep active and not to lie down It was believed that more nearly normal intracranial pressure was maintained by the erect position, thus preventing oversecretion and compensatory hypertension, with resultant headache

An excellent review and clinical survey of symptomatic neurosyphilis has been published by Solomon, Moore, O'Leary, Stokes and Thomas⁴⁰ It is pointed out that the symptoms of syphilis of the nervous system may simulate all forms and varieties of neuropsychiatric disorder Obviously, then in any disorder suggesting organic involvement of the nervous system neurosyphilis must be ruled out These authors divide neurosyphilis into two main categories meningo-vascular neurosyphilis, which produces little or no irreparable damage to nerve cells, except secondarily by interruption of the blood supply, and parenchymatous neurosyphilis Trivalent arsenicals and bismuth are of great benefit in meningo-vascular disease but not in parenchymatous neurosyphilis Obviously, the clinical distinction between the two is of great importance The symptoms of neurosyphilis are directly dependent on the site of involvement as well as on the extent of the lesion The clinical manifestations of the various types of neurosyphilis — syphilitic meningitis, meningo-vascular neurosyphilis, tabes dorsalis, general paresis, vascular neurosyphilis and congenital neurosyphilis — are described Tabes dorsalis and its sequelae are discussed at some length The great variety of symptoms that may be due to general paresis are emphasized Attention is directed to the fact that early stages of dementia paralytica are too easily and too frequently confused with psychoneurosis The treatment of each variety of neurosyphilis is discussed It is well known that parenchymatous neurosyphilis may be accompanied by negative spinal-fluid findings Seven cases of general paresis were recently reported in which a negative spinal-fluid Wassermann reaction⁴¹ occurred Several of these patients exhibited completely negative spinal fluids

(To be concluded)

infection. The possibility of superinfection although less likely, should always be kept in mind. Cases of supposed reinfection are five to ten times as frequent as in previous years.³³ The difficulty of adequately differentiating reinfection and relapse is illustrated by the variety of criteria that can be found postulated in the literature. The simplest criteria merely require proof of syphilis prior to the occurrence of the supposed second infection. This proof must consist of demonstration of spirochetes in the lesion or the occurrence of a positive blood serologic test and should not depend on clinical judgment alone. After an interval following anti-syphilitic treatment, and at a site other than that of the primary lesion of the first infection, there must develop a new lesion with the characteristics of a chancre and in which spirochetes can be demonstrated. From these simplest criteria, one can go to the opposite extreme of the seventeen complex criteria that are proposed by Stokes. In some diseases, reinfection can be considered a proof of cure of a preceding infection. Moore³² points out that this is not tenable with syphilis in human beings. After discussing the criteria of reinfection at some length, he states this opinion that, at the present time, re-infection cannot be differentiated from relapse on any grounds on which two or more observers would agree. He believes that this differentiation must rest on clinical impressions. This does not constitute proof. Moore points out that until order is brought out of the present confusion, all supposed reinfections must be regarded as treatment failures. This is especially applicable to the evaluation of new drugs and new treatment programs.

Syphilis of the Mouth

The various forms of syphilis of the mouth are discussed in some detail by Wilson, Dunning and Fox.³⁵ It is pointed out that the dentist has a large responsibility in discovering oral manifestations of systemic diseases. The oral lesions of primary, secondary and late syphilis, both acquired and congenital, are described, including those of the lips, tongue, oral cavity, teeth and palate. A differentiation from the usual nonsyphilitic diseases that may simulate syphilis of the mouth is given. Included in this list are aphthous stomatitis, herpes simplex, herpes zoster, pemphigus, erythema multiforme, lichen planus, lupus erythematosus, leukoplakia, lupus vulgaris, Vincent's infection, granuloma pyogenicum, epithelioma, lingua plicata, lingua geographica, dysvitaminosis, hypovitaminosis, avitaminosis, pellagra, fungous infections and perlèche. A word of caution has been written against overlooking the possibility of cancer of the tongue in patients with syphilis.³⁴ It is pointed out that cancer can exist in conjunction with syphilis of the tongue in any stage, but may be overshadowed by syphilis when the cancer is early. More frequent

biopsies of possibly suspicious areas would provide an earlier diagnosis of cancer and a greater percentage of cures. Needless to say, adequate treatment for coexisting syphilis must be diligently pursued.

Visceral Syphilis

O'Leary and Ockuly³⁵ point out that the only satisfactory method for determining that a lung lesion is syphilitic is a therapeutic test. The symptoms, physical signs and radiologic appearance of pulmonary syphilis are nondistinctive. When, however, a patient with positive serologic reactions is dyspneic, coughs, raises bloody sputum, has chest pain, is weak and loses weight and when physical and radiologic examinations indicate a nodular or infiltrative pulmonary process, one may presume that the lung lesion is syphilitic. If these signs and symptoms disappear after a course of therapy and do not recur, the opinion that the condition was syphilitic is tenable. In a series of 60 patients at the Mayo Clinic in which syphilis of the lung was considered a possibility, this diagnosis was substantiated in only 4 cases. Syphilis of the lung rarely recurs following involution under treatment.

Among 1705 consecutive adults admitted to a tuberculosis sanatorium for Negroes, 29.7 per cent were found to have positive serologic reactions for syphilis.³⁶ These patients were studied from a number of viewpoints without significant findings regarding a biologic relation between the two diseases. It has long been believed that the prognosis in such circumstances depends entirely on the tuberculosis, an opinion that was substantiated by this investigation.

Syphilis in diabetes has been studied by Perkin³⁷ over a five-year period. Among 550 diabetic patients comprising the series, 54 possible cases of syphilis (9.8 per cent) were found. The diabetes in the syphilitic group tended to be unusually mild. It is the author's opinion that syphilis, as well as all other so-called "causes" of diabetes, is merely a precipitating factor in the potential diabetic patient. These cases were observed for varying periods up to twelve years for changes in diabetic status. It is stated that there is some relation between latent syphilis in the diabetic patient and the occurrence of gangrene, but the supporting evidence is not too conclusive.

Neurosyphilis

An interesting study concerns the incidence of asymptomatic neurosyphilis in young men.³⁸ The data were obtained from the spinal-fluid findings of 3000 syphilitic military selectees passing through an induction station. Sufficient pathologic changes to cause rejection were found in 294 (9.5 per cent), all but 15 of whom had positive Wassermann reactions in the spinal fluid. The second most frequent abnormality was an increased globulin (174 cases). The colloidal gold curve was elevated in 92 cases,

3 Provision of adequate medical care for those unable to obtain it by voluntary prepayment plans or by direct payment is the responsibility of the local or state government. Part of the burden of this responsibility may be assumed by charitable agencies. Federal grants-in-aid to state programs administered by state boards of health is an acceptable method of helping to meet this responsibility.

4 The medical care of those who are able to purchase it by voluntary prepayment plans or by direct payment is the responsibility of the individual.

5 Eligibility for receiving benefits under a program aided by federal grants should be determined by the individual states.

6 The patient shall have free choice of his physician, group of physicians, clinic or hospital from among those participating in any plan, provided that the physician, group of physicians, clinic or hospital selected shall have the right to refuse or to accept the patient.

7 Physicians and other qualified persons rendering medical care shall receive adequate remuneration for their services.

8 The physician shall be free to elect or reject without prejudice participation in a medical-care plan. The rights of the physician as to the choice of methods by which he is to be paid shall be fully protected.

The committee recommends the adoption by the Council of the above basic principles as essential to the development of any successful medical-care plan and, as guides by which to evaluate medical-care plans that may be proposed in future, with the understanding that changing conditions may require their later revision.

Dr Root moved the adoption of this recommendation. This motion was seconded, and it was so ordered by vote of the Council.

The Maternal and Child Welfare Act of 1945 (Senate 1318) has been carefully studied by the subcommittee. Although this subcommittee is in complete agreement with the objectives stated in the introduction to the bill, "To provide for the general welfare by enabling the several states to make adequate provision for health and welfare of mothers and children and for services to crippled children," it finds serious objections to the bill as written. Some of the more important of these are as follows:

- (1) The bill makes no adequate provision for general public-health programs that are more fundamental than this specialized legislation.
- (2) Services and facilities are available to all who elect to participate, regardless of economic status. (This violates Basic Principles 4 and 5.)
- (3) The public deserves a reasonable estimate concerning the ultimate cost of this proposed legislation. Experience and such factual data as are available indicate an ultimate annual budget approximating one billion dollars. This should be clearly recognized in any consideration of the bill.
- (4) Fee-for-service method of payment is restricted to consultation or emergency visits and is not ordinarily available to practitioners or specialists.
- (5) The bill does not make clear just who is to decide the fee for a given service that would be considered adequate remuneration in an individual state, nor does it make provision for variable fees to meet the differing costs in the several states.
- (6) The bill does not prohibit professional personnel, groups or institutions rendering service under the program from accepting supplemental payment from or on behalf of patients.
- (7) The bill does not provide for payment to groups of physicians, clinics or hospitals providing professional services.
- (8) The bill does not emphasize the desirability of full utilization and further development of existing services and facilities.

(9) The bill does not emphasize the necessity of restricting the development and expansion of a state program to the capacity of available administrative and professional resources.

(10) This bill does not provide the professions with a continuing authoritative voice in the formulation of policies and plans. Such committees as are selected under the provisions of the bill may represent the attitude of the administrator rather than that of a given profession or group. (This violates Basic Principle 2.)

(11) The bill does not provide the facilities whereby the opinions of both the federal and state advisory committees are made available to the public.

(12) Designation of the Children's Bureau as the administrative agency does not adequately assure proper integration of the health activities of the federal government.

For these reasons the committee believes that this proposed act does not represent the best form of legislation for the purposes for which it was written. The committee recommends the adoption of this report on the Maternal and Child Welfare Act of 1945 (Senate 1318).

Dr Root moved the adoption of this recommendation. This motion was seconded, and it was so ordered by vote of the Council.

Senators Wagner and Murray introduced the National Health Act of 1945 (Senate 1606) in the Senate on November 19, 1945, the day of the reading of the President's message to Congress.

Title I of this bill authorizes grants-in-aid to states to (A) extend the public-health services, (B) increase maternal and child health services and (C) provide medical care for the needy.

Title II makes provision for full medical, dental, nursing and laboratory care and hospitalization for those able to pay for such services.

Because of the different provisions of the bill, it is desirable to discuss each part separately.

TITLE I GRANTS TO STATES FOR HEALTH SERVICES

Part A Grants to States for Public-Health Services

The Massachusetts Medical Society cites the progressive leadership that the physicians of New England have always shown in the development of public-health enterprises, and its adoption as a principle the making available to everyone every known essential, preventive, diagnostic and curative medical service of high quality. We do approve in general this part of the bill as written, with the following exceptions:

- (1) The responsibility for the training of personnel should be the duty of the states and not that of the federal government, as designated in Section 314A.
- (2) Provision should be made which would ensure proper representation of professional organizations on the advisory council (Section 314F).
- (3) Responsible private agencies, such as Blue Cross and Blue Shield, should be included among those with whom the state health agency may make working agreements (Section 314H).
- (4) The state administering agency should be required to consult with professional advisory committees before issuing regulations, which in turn should be issued only after due notice (Section 314H).

Part B Grants to States for Maternal and Child Health Services

It is the feeling of this committee that the objectives of this part of the bill are more clearly and completely covered in Senate Bill 1318. Earlier in this report we have stated the reasons for our disapproval of that bill as written.

Part C Grants to States for Medical Care of Needy Persons

We approve of federal grants to aid the several states in assuming their responsibility of providing medical care for those unable to pay for such services. We approve in general of this part of the bill as written with the following exceptions:

MASSACHUSETTS MEDICAL SOCIETY

SPECIAL MEETING OF THE COUNCIL

January 9, 1946

A SPECIAL meeting of the Council was called to order by the president, Dr Reginald Fitz, on Wednesday, January 9, 1946, at 3:00 p m, in John Ware Hall, 8 Fenway, Boston. Dr Michael A Tighe served as secretary.

The following councilors were present

The business before this meeting was the report of the Postwar Planning Committee, which concerned itself with certain basic principles considered essential to a medical-care plan, the Wagner-Murray-Dingell Act (Senate 1606), and the Maternal and Child Welfare Act of 1945 (Senate 1318).

The report of the committee presented by Dr Howard F Root, Suffolk, chairman, as amended and as adopted by the Council, is as follows

The committee and its subcommittees have held many meetings. The Subcommittee on Medical Economics has given intensive study to the Wagner Act (Senate 1606), to the Maternal and Child Welfare Act of 1945 (Senate 1318), to certain basic principles considered essential to a medical-care plan and to various methods of payment for medical services. For the purpose of informing the Society as a whole, its work has been summarized in the *New England Journal of Medicine*, issue of January 3, 1946. The committee believes that the following basic principles are essential to a medical-care plan in a free society

1 The objective of adequate medical care in our free society is to make available to everyone — regardless of race, color, creed, financial status, or place of residence — every known essential preventive, diagnostic and curative medical service of high quality. The attainment of such medical care must necessarily be an evolutionary process which will require the co-operation of all concerned over a period of years.

2 The success of any plan for medical care is dependent on the mutual co-operation of the public, those rendering professional services and the administrative agencies. This co-operation can be obtained only if those rendering the services are convinced that they will have a continuing authoritative voice in the formulation and execution of policies and plans, thereby assuming their proper share of responsibility.

3 Provision of adequate medical care for those unable to obtain it by voluntary prepayment plans or by direct payment is the responsibility of the local or state government. Part of the burden of this responsibility may be assumed by charitable agencies. Federal grants-in-aid to state programs administered by state boards of health is an acceptable method of helping to meet this responsibility.

4 The medical care of those who are able to purchase it by voluntary prepayment plans or by direct payment is the responsibility of the individual.

5 Eligibility for receiving benefits under a program aided by federal grants should be determined by the individual states.

6 The patient shall have free choice of his physician, group of physicians, clinic or hospital from among those participating in any plan, provided that the physician, group of physicians, clinic or hospital selected shall have the right to refuse or to accept the patient.

7 Physicians and other qualified persons rendering medical care shall receive adequate remuneration for their services.

8 The physician shall be free to elect or reject without prejudice participation in a medical-care plan. The rights of the physician as to the choice of methods by which he is to be paid shall be fully protected.

The committee recommends the adoption by the Council of the above basic principles as essential to the development of any successful medical-care plan and, as guides by which to evaluate medical-care plans that may be proposed in future, with the understanding that changing conditions may require their later revision.

Dr Root moved the adoption of this recommendation. This motion was seconded, and it was so ordered by vote of the Council.

The Maternal and Child Welfare Act of 1945 (Senate 1318) has been carefully studied by the subcommittee. Although this subcommittee is in complete agreement with the objectives stated in the introduction to the bill, "To provide for the general welfare by enabling the several states to make adequate provision for health and welfare of mothers and children and for services to crippled children," it finds serious objections to the bill as written. Some of the more important of these are as follows:

(1) The bill makes no adequate provision for general public-health programs that are more fundamental than this specialized legislation.

(2) Services and facilities are available to all who elect to participate, regardless of economic status. (This violates Basic Principles 4 and 5.)

(3) The public deserves a reasonable estimate concerning the ultimate cost of this proposed legislation. Experience and such factual data as are available indicate an ultimate annual budget approximating one billion dollars. This should be clearly recognized in any consideration of the bill.

(4) Fee-for-service method of payment is restricted to consultation or emergency visits and is not ordinarily available to practitioners or specialists.

(5) The bill does not make clear just who is to decide the fee for a given service that would be considered adequate remuneration in an individual state, nor does it make provision for variable fees to meet the differing costs in the several states.

(6) The bill does not prohibit professional personnel, groups or institutions rendering service under the program from accepting supplemental payment from or on behalf of patients.

(7) The bill does not provide for payment to groups of physicians, clinics or hospitals providing professional services.

(8) The bill does not emphasize the desirability of full utilization and further development of existing services and facilities.

(9) The bill does not emphasize the necessity of restricting the development and expansion of a state program to the capacity of available administrative and professional resources.

(10) This bill does not provide the professions with a continuing authoritative voice in the formulation of policies and plans. Such committees as are selected under the provisions of the bill may represent the attitude of the administrator rather than that of a given profession or group. (This violates Basic Principle 2.)

(11) The bill does not provide the facilities whereby the opinions of both the federal and state advisory committees are made available to the public.

(12) Designation of the Children's Bureau as the administrative agency does not adequately assure proper integration of the health activities of the federal government.

For these reasons the committee believes that this proposed act does not represent the best form of legislation for the purposes for which it was written. The committee recommends the adoption of this report on the Maternal and Child Welfare Act of 1945 (Senate 1318).

Dr Root moved the adoption of this recommendation. This motion was seconded, and it was so ordered by vote of the Council.

Senators Wagner and Murray introduced the National Health Act of 1945 (Senate 1606) in the Senate on November 19, 1945, the day of the reading of the President's message to Congress.

Title I of this bill authorizes grants-in-aid to states to (A) extend the public-health services, (B) increase maternal and child health services and (C) provide medical care for the needy.

Title II makes provision for full medical, dental, nursing and laboratory care and hospitalization for those able to pay for such services.

Because of the different provisions of the bill, it is desirable to discuss each part separately.

TITLE I GRANTS TO STATES FOR HEALTH SERVICES Part A Grants to States for Public-Health Services

The Massachusetts Medical Society cites the progressive leadership that the physicians of New England have always shown in the development of public-health enterprises, and its adoption as a principle the making available to everyone every known essential, preventive, diagnostic and curative medical service of high quality. We do approve in general this part of the bill as written, with the following exceptions:

(1) The responsibility for the training of personnel should be the duty of the states and not that of the federal government, as designated in Section 314A.

(2) Provision should be made which would ensure proper representation of professional organizations on the advisory council (Section 314F).

(3) Responsible private agencies, such as Blue Cross and Blue Shield, should be included among those with whom the state health agency may make working agreements (Section 314H).

(4) The state administering agency should be required to consult with professional advisory committees before issuing regulations, which in turn should be issued only after due notice (Section 314H).

Part B Grants to States for Maternal and Child Health Services

It is the feeling of this committee that the objectives of this part of the bill are more clearly and completely covered in Senate Bill 1318. Earlier in this report we have stated the reasons for our disapproval of that bill as written.

Part C Grants to States for Medical Care of Needy Persons

We approve of federal grants to aid the several states in assuming their responsibility of providing medical care for those unable to pay for such services. We approve in general of this part of the bill as written with the following exceptions:

MASSACHUSETTS MEDICAL SOCIETY

SPECIAL MEETING OF THE COUNCIL

January 9, 1946

A SPECIAL meeting of the Council was called to order by the president, Dr Reginald Fitz, on Wednesday, January 9, 1946, at 3 00 p m, in John Ware Hall, 8 Fenway, Boston Dr Michael A Tighe served as secretary

The following councilors were present

The business before this meeting was the report of the Postwar Planning Committee, which concerned itself with certain basic principles considered essential to a medical-care plan, the Wagner-Murray-Dingell Act (Senate 1606), and the Maternal and Child Welfare Act of 1945 (Senate 1318)

The report of the committee presented by Dr Howard F Root, Suffolk, chairman, as amended and as adopted by the Council, is as follows

The committee and its subcommittees have held many meetings. The Subcommittee on Medical Economics has given intensive study to the Wagner Act (Senate 1606), to the Maternal and Child Welfare Act of 1945 (Senate 1318), to certain basic principles considered essential to a medical-care plan and to various methods of payment for medical services. For the purpose of informing the Society as a whole, its work has been summarized in the *New England Journal of Medicine*, issue of January 3, 1946. The committee believes that the following basic principles are essential to a medical-care plan in a free society

1 The objective of adequate medical care in our free society is to make available to everyone — regardless of race, color, creed, financial status, or place of residence — every known essential preventive, diagnostic and curative medical service of high quality. The attainment of such medical care must necessarily be an evolutionary process which will require the co-operation of all concerned over a period of years

2 The success of any plan for medical care is dependent on the mutual co-operation of the public, those rendering professional services and the administrative agencies. This co-operation can be obtained only if those rendering the services are convinced that they will have a continuing authoritative voice in the formulation and execution of policies and plans, thereby assuming their proper share of responsibility.

CASE RECORDS OF THE MASSACHUSETTS GENERAL HOSPITAL

Weekly Clinicopathological Exercises

FOUNDED BY RICHARD C CABOT

TRACY B MALLORY, M D, *Editor*

BENJAMIN CASTLEMAN, M D, *Associate Editor*

EDITH E PARRIS, *Assistant Editor*

CASE 32101

PRESENTATION OF CASE

First admission A sixty-five-year-old unemployed man entered the hospital because of a chronic draining ulcer of the lower lateral aspect of the right leg

He had first been seen in the Orthopedic Clinic thirty-two years previously for a partially healed fracture of the right tibia just above the ankle. At that time an arthroplasty was performed and a metal plate was applied to the fibula. The ankle functioned well until about a year before admission when a bruise developed over the right external malleolus after a minor injury. This gradually spread, and nine months later the skin broke down there was constant drainage from the area thereafter. In the five years prior to admission he was seen many times in the Medical Clinic for a variety of complaints. Early in this period he had an episode of weakness, unproductive cough and fever lasting six weeks. His temperature during that time averaged 101°F. There was no sweating. He was well for several months and then had an attack of "bronchitis," during which he had chills, a fever rising to 104°F and blood-streaked sputum for a period of three weeks. In addition to these febrile attacks he developed mild dyspnea on exertion and swelling of the ankles, most pronounced in the evening. At the same time he was troubled by difficulty in starting the urinary stream and by nocturia (one or two times). There were also numerous episodes of vague epigastric distress, with sensations of fullness and discomfort, sometimes accompanied by shortness of breath. X-ray examination of the chest at this hospital four years before admission showed clear lung fields. The cardiac pulsations were said to be extremely small. An electrocardiogram showed a PR interval of 0.16 second, a flat T₁, inverted T₂ and T₃ and a low T₄. The blood pressure on three occasions was 112 systolic, 90 diastolic, 100 systolic, 70 diastolic, and 80 systolic, 70 diastolic. The liver was palpable three fingerbreadths below the rib margin. He received 0.1 gm of digitalis daily during the

four-year period before admission, but continued to have episodes of ankle edema, swelling of the lower abdomen and dyspnea on moderate exertion. He stayed in bed for one to six weeks at times when these symptoms were at their worst.

Physical examination showed marked pigmentation and a 1-cm ulcer on the lateral aspect of the right fibula. The head of a screw was visible in the floor of the ulcer. There were scattered rales at the lung bases. The heart was normal.

The temperature was 97°F, the pulse 80, and the respirations 20. The blood pressure was 120 systolic, 88 diastolic.

An x-ray film of the ankle showed bone absorption and periosteal proliferation about the metal plate. The lower end was free in the soft tissues. A chest plate showed hazy density of the left lower lung field. The left leaf of the diaphragm could not be visualized. The heart was in transverse position and appeared slightly enlarged to the left. There was no change in the electrocardiographic findings from the previous examination.

The bone plate was removed, and the wound healed slowly. A thoracentesis on the left side yielded 35 cc of clear yellow fluid, which was negative for tumor cells, a guinea pig inoculated with it failed to develop tuberculosis.

Second admission (five months later) One month prior to this admission the patient developed pain in the left side of the chest, which persisted. It began at a point just below and lateral to the nipple and extended to a point just below the angle of the scapula. At first it was aggravated by deep respiration, but it was gradually reduced to a dull, constant ache. He lost 10 pounds in the month prior to entry. There was no cough or sensation of fever, although exertional dyspnea persisted.

On examination of the chest there were flatness and absent tactile fremitus and greatly diminished breath sounds over the lower half of the left chest. The temperature was 100°F.

Seven hundred and twenty cubic centimeters of bloody, cloudy fluid was removed through the ninth left intercostal space. The patient was discharged unimproved except that his temperature was normal on the fifth hospital day.

Third admission (six months later) The chest pain persisted after discharge except for periods of one to three days after each of four thoracenteses performed in the Emergency Ward. They yielded diminishing amounts of fluid, and after each a friction rub was heard. There had been no further weight loss, nor had cough or other symptoms developed.

The trachea was deviated slightly to the left. The first heart sound at the apex was slapping in character. The pulmonic second sound was split giving an apparent systolic gallop. The left side of the thorax was flatter than the right and moved

(1) We believe that all federal grants-in-aid for the medical care of needy persons should be made by the United States Public Health Service to state departments of public health until such time as these grants may be made by a federal Department of Public Health

(2) We disapprove of the provision that places the responsibility in the Social Security Board on the federal level and in the Department of Welfare on a state level (Section 131)

(3) This Society through its Blue Shield has approved of the service principle rather than the payment to patients of cash benefits for medical care. We disapprove of the provision in the bill of making cash payments to individuals for this purpose

TITLE II PREPAID PERSONAL HEALTH-SERVICE BENEFITS

This is compulsory health insurance. It would be very costly to carry out the provisions of this section of the bill, and there is nothing to intimate what this will add to the burden of the taxpayer or how the money will be raised. Since we believe that the payment for medical care of those able to pay for such services by direct payment or on a prepayment basis is the responsibility of the individual and that with the extension and development of voluntary prepayment or other plans particularly adapted to certain areas, medical care of the highest quality can be obtained at a reasonable cost, we disapprove of this section

* * *

The Committee on Postwar Planning recommends that the Council direct the president of the Society to appoint a representative and an alternate to appear before the appropriate committees of the Congress of the United States for the purpose of making known the views of the

Massachusetts Medical Society with regard to the Wagner-Murray-Dingell Bill (Senate 1606) and the Maternal and Child Welfare Act of 1945 (Senate 1318)

Dr. Root moved the adoption of this recommendation. This motion was seconded, and it was so ordered by vote of the Council

The committee further recommends that the Council send copies of the article "Information on the Deliberations of the Subcommittee on Medical Economics," together with the action of the Council of the Massachusetts Medical Society, to all the members of the Congress of the United States, to the members of the Massachusetts Legislature and to the newspapers of the Commonwealth

Dr. Root moved the adoption of this recommendation. This motion was seconded, and it was so ordered by vote of the Council

It was moved by Dr. Leroy E. Parkins, Suffolk, and seconded, that the members of the various committees who had spent so many long hours of vigilant effort in preparing this report be given a vote of thanks. This motion was amended so as to include the President for his expert guidance. The motion was adopted by vote of the Council

The Council adjourned at 6:35 p.m.

MICHAEL A. TIGHE, *Secretary*

So far as the findings by x-ray are concerned there was what was called a thickened pleura, which persisted over a long period of time. The heart was displaced toward the affected side, and it looks as if there was some underlying lung condition, because they describe a partial collapse of the lower lobe.

So far as the heart is concerned there were dyspnea, cyanosis, edema of the ankles, a large liver and fluid in the abdomen. That concludes the story of his symptoms, but along with that we are given a good deal of information. They tell us that he had small cardiac pulsations, a low blood pressure, a low pulse pressure and electrocardiographic findings that, to my knowledge, are consistent with constrictive pericarditis. I do not see how one can get away from such a diagnosis. Except for the pericardial changes, I cannot see how the heart was involved. This man was sixty-five years old. I grant that that is above the average for constrictive pericarditis, but it can happen at that age.

Let us look at the lung films and guess as much as we can about the lung condition.

DR. MILFORD D. SCHULZ: The earliest chest film that I can find is a lateral view taken in 1943, three years before his death.

DR. KING: I think that it shows some involvement in the lung base.

DR. SCHULZ: I agree. In the 1944 films you can see collapse of the left lower lobe and some pleural deformity on each side. In those of 1945, there is a newly developed density described as being in the dorsal division of the lower lobe. I wonder, however, if it is not in the basal portion of the upper lobe.

DR. KING: All you can say is that he had partial collapse of the lower lobe and pleural involvement?

DR. SCHULZ: Yes. I am looking for calcification in the pericardium, but I do not see any.

DR. KING: These are the films on the last admission, when he came in with what I should say was an acute pneumococcal pneumonia, which I am going to add on top of the old process. He had plenty of Type 3 pneumococci in the throat, not actually in the sputum. Does that not look more like an acute pneumonic process than an infarct?

DR. SCHULZ: Yes. If it is an infarct, it is a big one.

DR. KING: Would you be willing to agree that these films are consistent with an acute pneumonia that later spread to the apex of the lung?

DR. SCHULZ: Yes, that is what I thought it was when I looked at it.

DR. KING: So far as the pleural process is concerned, I do not know of anything that will give a pleural reaction of this severity and duration and with fluid except tuberculosis. And if one accepts that diagnosis for the pleurisy, one had best accept it also for the pericarditis. The literature tells of constrictive pleuritis, as well as constrictive peri-

carditis, but there is no evidence of constrictive pleuritis here.

I realize that two pieces of evidence have been given that are against the diagnosis of tuberculosis—a negative guinea-pig inoculation of the chest fluid and a negative biopsy of the pleura. But 35 cc of fluid is too small an amount for satisfactory examination for tubercle bacilli, especially if one also looks for tumor cells, and although I am not sure of this, I believe that a tuberculous pleurisy may in certain areas show only collagenous tissue, with no definite tubercles. I realize, too, that when pericarditis and pleuritis occur together they are often idiopathic and are never adequately explained. Nevertheless I still hold to the diagnosis of tuberculosis of the pleura and pericardium.

The diagnosis of tuberculosis of the lung is still more difficult to substantiate, but I shall guess that there was tuberculosis in the partially collapsed lobe. It is also possible that at death there was considerable tuberculosis outside this area, but we have no proof of that. Apparently the sputum was not examined for tubercle bacilli—a too frequent oversight. I find that these days the first thought is for the chemical constituents, and sputum examination is often not thought of. Speaking of the chemical findings, the albumin-globulin ratio in this case is consistent with constrictive pericarditis.

Next there is the liver. Did he have cirrhosis? And was it a true Pick's disease—mediastino-pericarditic pseudo-cirrhosis of the liver? I suppose that that is what he had. Did he also have chronic peritonitis, which is frequent in these cases? Again, in a long-standing case of this sort I suppose that he did.

When he came to die, I think that he had a Type 3 pneumococcus pneumonia and that he died from a pulmonary embolus. I do not see how we can prove that he had infarcts in the lung, but I believe that he probably did have them.

All of which gives us a great many diagnoses, but I seem forced to take them all—tuberculous constrictive pericarditis, tuberculous pleurisy, pulmonary tuberculosis, pulmonary embolus (fatal), pulmonary infarcts, Type 3 pneumococcus pneumonia and "pseudo-cirrhosis of the liver."

DR. EDWARD F. BLAND: Is there any mention made of cervical veins?

DR. KING: I do not know why we are not given the venous pressure. It would be a help. Whether I can assume they were normal, I do not know.

I am interested to know if you would make a diagnosis of constrictive pericarditis, Dr. Bland?

DR. BLAND: I do not believe so.

DR. KING: Perhaps you know too much about the case.

DR. BLAND: No.

DR. ALBERT J. STUNKARD: The patient had no

poorly. The percussion note in the left axilla and lower half of the left chest was flat, breath sounds and tactile fremitus were diminished. The left side of the diaphragm did not appear to move. The liver was palpable two fingerbreadths below the ribs. X-ray examination revealed a markedly thickened pleura on the left side, with probable partial underlying collapse of the left lobe. The heart was displaced to the left, and there was a small amount of free fluid just above the diaphragm.
